CONTENTS

PAPERS

No. PAGE

2056 **WIND FORCES ON A TALL BUILDING.**

By **J. Charles Rathbun** 1

Discussion:

By David Cushman Coyle 42
Clyde T. Morris 44
Robins Fleming 44
F. P. Shearwood 49
Lydik S. Jacobsen 50
Francis L. Castleman, Jr. 52
J. B. Wilbur 55
R. D. Spellman 57
David A. Molitor 58
Walter J. Gray 60
K. L. DeBlois 60
Albert Smith 61
Victor R. Bergman 64
Otto Gottschalk 65
Colin Skinner 65
J. Charles Rathbun 77

2057 **ANALYSIS OF RUN-OFF CHARACTERISTICS.**

By **Otto H. Meyer** 83

Discussion:

By Victor H. Cochrane 101
Bertram S. Barnes 104
LeRoy K. Sherman 106
Richmond T. Zoch 109
Merrill Bernard 117
Franklin F. Snyder 122
W. G. Hoyt 127
C. O. Clark 128
C. S. Jarvis 131
Howard M. Turner 134
Otto H. Meyer 138

2058 **SPECIFICATION AND DESIGN OF STEEL GUSSET-PLATES.**

By **T. H. Rust** 142

Discussion:

By R. H. Sherlock 159
L. E. Grinter 159
Russell C. Brinker 161
C. W. Wixom 162
T. H. Rust 163

2059 **GREAT LAKES TRANSPORTATION.**

By **M. C. Tyler** 167

Discussion:

By T. Kennard Thomson 186
Harland C. Woods 188
W. L. R. Haines 188
L. C. Sabin 193

No. PAGE

2060 **TESTS ON BUILT-UP COLUMNS OF STRUCTURAL ALUMINUM ALLOYS.**
By Marshall Holt 196
Discussion:
By Alfred S. Niles 218
Marshall Holt 219

2061 **TRANSPORTATION DEVELOPMENTS IN THE UNITED STATES.**
By Fred Lavis 220
Discussion:
By Milton Harris 237
Ralph Budd 239
L. Alfred Jenny 243
William J. Cunningham 256
S. R. Truesdell 257
David A. Molitor 259
C. A. Hoglund 263
Fred Lavis 266

2062 **EARTHQUAKES AND STRUCTURES.**
By Leander M. Hoskins and John D. Galloway 269
Discussion:
By Homer M. Hadley 298
R. McC. Beanfield 300
R. S. Chew 303
Jacob J. Creskoff 305
Arthur C. Ruge 307
Walter L. Huber 309
A. A. Eremin 314
Henry D. Dewell 315
John D. Galloway and Lydik S. Jacobsen 319

2063 **TRAFFIC PROBLEMS IN METROPOLITAN AREAS.**
By Earl J. Reeder 323
Discussion:
By George H. Herrold 331
Thomas Buckley 333
D. Grant Mickle 336
Robert A. Mitchell 339
Cleveland B. Coe 342
Earl J. Reeder 343

2064 **THE YELLOW RIVER PROBLEM.**
By O. J. Todd and S. Eliassen 346
Discussion:
By J. W. Beardsley 417
Elliott J. Dent 418
Herbert Chatley 425
H. van der Veen 427
C. S. Jarvis 433
E. W. Lane 434
George Higgins 441
O. J. Todd and S. Eliassen 443

2065 **THE RISK OF THE UNEXPECTED IN SUB-SURFACE CONSTRUCTION CONTRACTS.**
By Oren Clive Herwitz 454
Discussion:
By Alonzo J. Hammond 476
Frederick W. Newton 477

No. Page

David A. Molitor 488
F. B. Marsh 489
Evan S. Martin 490
C. Maxwell Stanley 490
Francis J. Morgan and Frederick C. Zeigler 492
Lazarus White 495
T. Kennard Thomson 497
Carroll A. Farwell 499
Oren Clive Herwitz 501

2066 **DESIGN OF CIRCULAR CONCRETE TANKS.**

By **George S. Salter** 504

Discussion:

By Carl A. Rosengarten 514
I. K. Silverman 515
Frank J. McCormick 517
H. B. Muckleston 518
Robert B. B. Moorman 519
Dana Young 521
L. J. Mensch 524
Jens Egede Nielsen 526
Lloyd S. Dysland 527
Basil Sourochnikoff 528
Regis F. Fey 529
George S. Salter 530

2067 **STATE-WIDE SURVEYING PRACTICE IN MASSACHUSETTS: A SYMPOSIUM** 533

ESTABLISHING A SYSTEM OF RECTANGULAR CO-ORDINATES.

By **Elmer C. Houdlette** 534

THE LAND COURT AND ITS ENGINEERING PROCEDURE.

By **Clarence B. Humphrey** 554

Discussion:

By H. J. Shea 565
Philip Kissam 568
Lloyd G. Frost 569
William Bowie 574
R. M. Wilson 578
Elliott B. Roberts 579

2068 **ENGINEERING GEOLOGY PROBLEMS AT CONCHAS DAM, NEW MEXICO.**

By **Irving B. Crosby** 581

Discussion:

By H. L. Johnson 600
Irving B. Crosby 604

2069 **LATERAL SPILLWAY CHANNELS.**

By **Thomas R. Camp** 606

Discussion:

By W. E. Howland 618
Lewis V. Carpenter, John K. Vennard, and Fenner H. Whitley 621
F. Knapp 625
Carl Rohwer 626
Harold Allen Thomas, Jr. 627
Thomas R. Camp 633

No. PAGE

2070 THEORY OF LIMIT DESIGN.

By **J. A. Van den Broek** 638

Discussion:

By JOHN H. MEURSINGE 662
I. K. SILVERMAN 665
EDWARD GODFREY 667
BASIL SOUROCHNIKOFF 668
E. MIRABELLI 670
C. M. GOODRICH 672
GEORGE WINTER 673
FRANCIS E. SIMPSON 679
JOSEPH A. WISE 680
ALFRED FREUDENTHAL 686
HANS H. BLEICH 690
ALFRED S. NILES 693
A. FLORIS 700
L. H. NISHKIAN 702
F. G. ERIC PETERSON 706
E. S. FABIAN 710
A. A. EREMIN 713
L. H. DONNELL 713
J. A. VAN DEN BROEK 717

2071 PROPOSED IMPROVEMENTS FOR LAND SURVEYS AND TITLE TRANSFERS.

By **Philip Kissam** 731

Discussion:

By GEORGE D. WHITMORE 741
PHILIP KISSAM 742

2072 DESIGN OF AN OPEN-CHANNEL CONTROL SECTION.

By **Karl R. Kennison** 744

Discussion:

By V. L. STREETER 752
EMERY H. WILLES 753
ROBERT O. THOMAS 755
FRANK S. BAILEY 757
GEORGE E. BARNES 758
KARL R. KENNISON 763

2073 GRAPHICAL ARCH ANALYSIS APPLICABLE TO ARCH DAMS.

By **Carl H. Heilbron, Jr., and William H. Saylor** 765

Discussion:

By I. M. NELIDOV 790
CARL H. HEILBRON, JR., AND WILLIAM H. SAYLOR 792

2074 HYDROLOGY OF THE GREAT LAKES: A SYMPOSIUM 794

TYPICAL QUANTITATIVE ANALYSIS AS APPLIED TO LAKE SUPERIOR.

By **C. R. Pettis** 795

EVAPORATION EXPERIMENTS.

By **Harold C. Hickman** 807

Discussion:

By A. A. YOUNG 818
ALFRED J. COOPER, JR. 821
ADOLPH F. MEYER 825
S. T. HARDING 829

No. Page

O. E. Meinzer 834
R. W. Davenport 835
G. H. Hickox 838
C. R. Pettis 842
Harold C. Hickman 845

2075 **LARGE CORE DRILLS AID CONSTRUCTION AT CHICKAMAUGA DAM.**
By **James S. Lewis, Jr.** 850

Discussion:
By J. B. Newsom 865
J. G. Tripp 865
James B. Hays 866
O. N. Floyd 867
James S. Lewis, Jr. 868

2076 **BEACH EROSION STUDIES.**
By **Earl I. Brown** 869

Discussion:
By Morris N. Lipp 891
George A. Soper 893
James J. O'Rourke 895
Elliott J. Dent 898
Ralph F. Rhodes 901
Charles T. Leeds 905
Earl I. Brown 913

2077 **SETTLEMENT STUDIES OF STRUCTURES IN EGYPT.**
By **Gregory P. Tschebotareff** 919

Discussion:
By L. C. Wilcoxen 946
Trent R. Dames 946
Edwin J. Beugler 950
W. S. Hanna 951
D. P. Krynine 954
Gregory P. Tschebotareff 958

2078 **POLLUTION OF BOSTON HARBOR.**
By **Arthur D. Weston and Gail P. Edwards** 973

Discussion:
By E. Sherman Chase 1009
F. E. DeMartini 1010
A. M. Rawn 1012
Harrison P. Eddy, Jr., and Samuel A. Greeley 1012
George A. Soper 1016
Arthur D. Weston and Gail P. Edwards 1017

2079 **SIMPLIFIED WIND-STRESS ANALYSIS OF TALL BUILDINGS.**
By **Otto Gottschalk** 1019

Discussion:
By Samuel T. Carpenter 1029
Charles B. Winick 1030
Otto Gottschalk 1035

2080 **DESIGN OF A HIGH-HEAD SIPHON SPILLWAY.**
By **Elmer Rock** 1050

Discussion:
By J. C. Stevens 1062
B. E. Torpen, G. E. Hyde, and R. B. Cochrane 1063
I. M. Nelidov 1066
Elmer Rock 1071

No. Page

2081 **DESIGN OF DOWELS IN TRANSVERSE JOINTS OF CONCRETE PAVEMENTS.**

By **Bengt F. Friberg** 1076

Discussion:

By L. E. Grinter 1096

W. O. Fremont 1102

Bengt F. Friberg 1111

2082 **STRESS DISTRIBUTION AROUND A TUNNEL.**

By **Raymond D. Mindlin** 1117

Discussion:

By W. O. Richmond 1141

Jacob Feld 1143

J. H. A. Brahtz 1143

Raymond D. Mindlin 1152

2083 **THE UNIT HYDROGRAPH PRINCIPLE APPLIED TO SMALL WATERSHEDS.**

By **E. F. Brater** 1154

Discussion:

By Franklin F. Snyder 1179

LeRoy K. Sherman 1181

Raphael G. Kazmann 1183

Waldo E. Smith 1184

E. F. Brater 1188

2084 **TENSION TESTS OF LARGE RIVETED JOINTS.**

By **Raymond E. Davis, Glenn B. Woodruff, and Harmer E. Davis** ... 1193

Discussion:

By Charles F. Goodrich 1246

Frederick P. Shearwood 1249

Jonathan Jones 1253

C. C. Winter 1261

W. M. Wilson 1264

J. M. Garrelts 1275

A. E. Richard de Jonge 1275

E. C. Hartmann and Marshall Holt 1291

Raymond E. Davis, Glenn B. Woodruff, and Harmer E. Davis . 1295

2085 **COMBINING GEODETIC SURVEY METHODS WITH CADASTRAL SURVEYS.**

By **Carl M. Berry** 1300

Discussion:

By William L. Sawyer 1331

Philip Kissam 1331

Gordon Macleish 1333

Carl M. Berry 1341

2086 **DEVELOPMENT OF THE COLORADO RIVER IN THE UPPER BASIN.**

By **Thomas C. Adams** 1345

Discussion:

By C. C. Elder 1366

Thomas C. Adams 1370

2087 **AN IMPROVED METHOD FOR ADJUSTING LEVEL AND TRAVERSE SURVEYS.**

By **Clarence Norris and Julius L. Speert** 1376

Discussion:

By George H. Dell 1395

Howard S. Rappleye 1398

No. PAGE
R. M. Wilson 1399
Cleveland B. Coe 1401
George D. Whitmore, C. C. Miner, and W. O. Byrd 1405
Robert C. Sheldon 1407
Clarence Norris and Julius L. Speert 1408

2088 **FLASH-BOARD PINS.**

By **Chilton A. Wright and Clifford A. Betts** 1412

Discussion :
By William P. Creager 1445
Lincoln W. Ryder 1445
E. T. Schuleen 1447
John E. Field 1451
Julian H. White 1452
Harry H. Hatch 1458
Chilton A. Wright and Clifford A. Betts 1458

2089 **EFFECTIVE MOMENT OF INERTIA OF A RIVETED PLATE GIRDER.**

By **Scott B. Lilly and Samuel T. Carpenter** 1462

Discussion :
By William R. Osgood 1477
Clyde T. Morris 1477
B. R. Leffler 1478
E. Neil W. Lane 1480
Lewis E. Moore 1481
W. E. Black 1482
L. E. Grinter 1484
Charles M. Spofford 1488
E. Mirabelli 1489
Edward Godfrey 1491
Walter H. Weiskopf 1493
C. D. Williams 1494
Alvin B. Auerbach 1496
Jonathan Jones 1498
R. L. Moore 1499
J. M. Garrelts and I. E. Madsen 1501
Francis P. Witmer 1504
A. W. Fischer 1505
J. R. Shank 1506
Harold D. Hussey 1508
Charles U. Kring 1511
Thomas C. Shedd 1512
Scott B. Lilly and Samuel T. Carpenter 1515

2090 **FIELD TESTS OF A SHALE FOUNDATION.**

By **August E. Niederhoff** 1519

Discussion :
By Harry H. Hatch 1535
Jacob Feld 1537
Jack R. Rountree 1538
August E. Niederhoff 1543

2091 **RELATION OF THE STATISTICAL THEORY OF TURBULENCE TO HYDRAULICS.**

By **A. A. Kalinske** 1547

Discussion :
By Hunter Rouse 1567
Martin A. Mason 1568
J. C. Stevens 1571

No. PAGE

BORIS A. BAKHMETEFF 1572
CLYDE W. HUBBARD 1574
JOHN S. MCNOWN 1576
SAMUEL SHULITS 1578
PAUL NEMENYI 1581
BENNIE N. NETZER 1591
A. A. KALINSKE 1593

2092 **SEWAGE DISPOSAL PROJECT OF BUFFALO, NEW YORK.**
By **Samuel A. Greeley** 1601

Discussion:
By C. A. HOLMQUIST 1626
ARTHUR J. BULGER 1628
C. R. VELZY 1629
THOMAS M. NILES 1634
SAMUEL A. GREELEY 1636

2093 **FUNCTIONAL DESIGN OF FLOOD CONTROL RESERVOIRS.**
By **C. J. Posey and Fu-Te I** 1638

Discussion:
By EDWARD SOUCEK 1648
J. C. STEVENS 1649
EDWARD J. BEDNARSKI 1652
ROLAND A. KAMPMEIER 1655
EDGAR E. FOSTER 1656
SHERMAN M. WOODWARD 1658
M. KINDINGER 1658
P. WILHELM WERNER 1662
WALDO E. SMITH 1665
J. O. JONES 1669
W. C. HAMMATT 1670
C. J. POSEY AND FU-TE I 1671

2094 **RECONSTRUCTION OF THE WALPOLE-BELLOWS FALLS ARCH BRIDGE.**
By **H. E. Langley and Edward J. Ducey** 1675

Discussion:
By J. B. FRENCH 1701
LEWIS D RIGHTS 1701
CONDE B. MCCULLOUGH 1702
H. M. NELSON 1707
H. E. LANGLEY AND EDWARD J. DUCEY 1708

2095 **FINAL REPORT OF SUB-COMMITTEE NO. 31, COMMITTEE ON STEEL OF THE STRUCTURAL DIVISION, ON WIND BRACING IN STEEL BUILDINGS** 1713

2096 **REPORT OF THE COMMITTEE ON WATER SUPPLY ENGINEERING OF THE SANITARY ENGINEERING DIVISION: IMPORTANT EVENTS, DEVELOPMENTS, AND TRENDS IN WATER SUPPLY ENGINEERING DURING THE DECADE ENDING WITH THE YEAR 1939** 1740

2097 **THE RELATION OF THE SOCIETY TO NATIONAL DEFENSE: ADDRESS AT THE ANNUAL CONVENTION, DENVER, COLORADO, JULY 24, 1940.**
By **John P. Hogan** 1781

XI

MEMOIRS OF DECEASED MEMBERS

	Page
Charles David Marx, Past-President and Hon. M. Am. Soc. C. E.	1785
Gustav Lindenthal, Hon. M. Am. Soc. C. E.	1790
Henry Bissell Alvord, M. Am. Soc. C. E.	1794
James MacFarlane Angle, M. Am. Soc. C. E.	1796
William John Ash, M. Am. Soc. C. E.	1798
Calvin Lewis Barton, M. Am. Soc. C. E.	1799
George Erle Beggs, M. Am. Soc. C. E.	1800
James C. Bell, M. Am. Soc. C. E.	1803
John George Bloom, M. Am. Soc. C. E.	1805
Norman Freed Brown, M. Am. Soc. C. E.	1806
Everett N. Bryan, M. Am. Soc. C. E.	1808
Walter Carl Buetow, M. Am. Soc. C. E.	1810
Ralph Howe Cady, M. Am. Soc. C. E.	1811
Thomas Jenks Carlile, M. Am. Soc. C. E.	1813
Allan Winter Cuddeback, M. Am. Soc. C. E.	1815
James Eugene Curtis, M. Am. Soc. C. E.	1818
Walter Whaley Curtis, M. Am. Soc. C. E.	1819
William Channing Cushing, M. Am. Soc. C. E.	1820
Cornelius Mark Daily, M. Am. Soc. C. E.	1824
John Vipond Davies, M. Am. Soc. C. E.	1826
Daniel Young Dimon, M. Am. Soc. C. E.	1828
Walter Alexander Doane, M. Am. Soc. C. E.	1830
Guy Carleton Emerson, M. Am. Soc. C. E.	1833
John Farris, M. Am. Soc. C. E.	1835
Howell Tracy Fisher, M. Am. Soc. C. E.	1837
Louis Prevost Gaston, M. Am. Soc. C. E.	1838
George Gibbs, M. Am. Soc. C. E.	1840
Ralph Edward Goodwin, M. Am. Soc. C. E.	1844
Roy Cotsworth Gowdy, M. Am. Soc. C. E.	1846
Edward Francis Haas, M. Am. Soc. C. E.	1851
Ephraim Harrington, M. Am. Soc. C. E.	1854
Philip Hart, M. Am. Soc. C. E.	1855
Ralph Stevenson Hawley, M. Am. Soc. C. E.	1861
William Chauncey Hawley, M. Am. Soc. C. E.	1863
James Clark Irwin, M. Am. Soc. C. E.	1864
Charles White Johns, M. Am. Soc. C. E.	1866
Arthur Newhall Johnson, M. Am. Soc. C. E.	1868
Richard Khuen, Jr., M. Am. Soc. C. E.	1869
Philip George Lang, Jr., M. Am. Soc. C. E.	1871
William Dominick Larrabee, M. Am. Soc. C. E.	1875
Arthur Hermann Markwart, M. Am. Soc. C. E.	1877
Frederick Mears, M. Am. Soc. C. E.	1881
Samuel Phillips Mitchell, M. Am. Soc. C. E.	1886
Charles Nicholas Monsarrat, M. Am. Soc. C. E.	1889

ERRATA

Transactions, Vol. 99 (1934)

Page 483, delete Footnote 53 and substitute the following:

[53] “Critical Review of the Literature on Riveted Joints,” by A. E. R. de Jonge, *Research Publications*, A.S.M.E., 1940 (publication pending).

PAPERS AND REPORTS OF COMMITTEES PUBLISHED IN PROCEEDINGS, AM. SOC. C. E., OCTOBER, 1939, TO SEPTEMBER, 1940, INCLUSIVE, NOT PUBLISHED IN TRANSACTIONS, VOL. 105

	Number of *Proceedings*.
GENERAL WEDGE THEORY OF EARTH PRESSURE. By Karl Terzaghi	October, 1939
THE RÔLE OF THE ENGINEER IN AIR SANITATION: A SYMPOSIUM	November, 1939
PROBLEMS AND TRENDS IN ACTIVATED SLUDGE PRACTICE. By Robert T. Regester	November, 1939
BRIDGE AND TUNNEL APPROACHES. By John F. Curtin	November, 1939
TREND IN HYDRAULIC TURBINE PRACTICE: A SYMPOSIUM	November, 1939
EFFECTS OF RIFLING ON FOUR-INCH PIPE TRANSPORTING SOLIDS. By G. W. Howard	November, 1939
TRANSIENT FLOOD PEAKS. By Henry B. Lynch	November, 1939
CHANNELIZATION OF MOTOR TRAFFIC. By Guy Kelcey	December, 1939
WATER SUPPLY ON UPPER SALT RIVER, ARIZONA. By John Girand	December, 1939
ANALYSIS OF LEGAL CONCEPTS OF SUBFLOW AND PERCOLATING WATERS. By C. F. Tolman and Amy C. Stipp	December, 1939
MINIATURE SYSTEM OF FIRST-ORDER ALINEMENT AND TRIANGULATION CONTROL. By Floyd W. Hough	December, 1939
PRESSURE-MOMENTUM THEORY APPLIED TO THE BROAD-CRESTED WEIR. By H. A. Doeringsfeld and C. L. Barker	December, 1939
NORRIS DAM CONSTRUCTION CABLEWAYS. By R. T. Colburn and L. A. Schmidt, Jr.	December, 1939
STANDARDS OF PROFESSIONAL RELATIONS AND CONDUCT. By Daniel W. Mead	January, 1940
THEORY OF ELASTIC STABILITY APPLIED TO STRUCTURAL DESIGN. By Leon S. Moisseiff and Frederick Lienhard	January, 1940

Number of *Proceedings.*

CHICAGO RIVER CONTROL WORKS.
By H. P. Ramey .... January, 1940

AXIOMS IN ROADWAY SOIL MECHANICS.
By Henry C. Porter .... February, 1940

MEASURING THE POTENTIAL TRAFFIC OF A PROPOSED VEHICULAR CROSSING.
By N. Cherniack .... February, 1940

WIND FORCES ON A TALL BUILDING

By J. Charles Rathbun,[1] M. Am. Soc. C. E.

With Discussion by Messrs. David Cushman Coyle, Clyde T. Morris, Robins Fleming, F. P. Shearwood, Lydik S. Jacobsen, Francis L. Castleman, Jr., J. B. Wilbur, R. D. Spellman, David A. Molitor, Walter J. Gray, K. L. DeBlois, Albert Smith, Victor R. Bergman, Otto Gottschalk, Colin Skinner, and J. Charles Rathbun.

Synopsis

Since the construction of the Empire State Building in New York, N. Y., considerable data have been collected pertaining to the intensity and distribution of the wind pressure during storms, as observed by instruments placed in this structure. At the same time the movement of the top of the building and the stresses in some of the members of the frame have been observed.

A model of the steel frame was constructed and measurements of its deformation under horizontal load, as well as its period of vibration, were noted. From these observations the actual lateral loads on the building were estimated under certain assumptions. The ratio between the stiffness of the building and its frame (acting alone) was then computed to give an indication of the percentage of the load that is carried by the frame. The plastic as well as the elastic action of the structure is indicated in the data.

The following studies were contemplated when this set of experiments was undertaken:

(*a*) The relation between the velocity of the wind and the pressure produced;
(*b*) The variation of stresses due to wind across a bent;
(*c*) A check, or refutation, of the basic principles of the portal and cantilever methods of analysis; and
(*d*) An estimate of the proper horizontal load that should be used in designing a tall building to insure proper rigidity and stability.

Because of the erratic nature of the data, definite conclusions have not been reached in the solution of these problems.

The instruments installed in the building for the special purposes of the observations were: 1 anemometer; 30 manometers; 28 cameras with operating mechanism; 22 extensometers; 1 collimator and target; and 1 plumb-bob.

Note.—Published in September, 1938, *Proceedings*.

[1] Associate Prof., Civ. Eng., Coll. of the City of New York, New York, N. Y.

The paper is divided into three parts. Part I contains a discussion of: (*a*) The nature of the wind and the pressure produced by it; and also (*b*) the deflection and stresses in the building due to wind action. Part II gives an estimate of the stiffening effect of the masonry on the steel and an approximate evaluation of the uniform load on the structure due to the wind. A model, with its equipment, was tested in the laboratory for the investigation described in Part II. Finally, Part III cites nine concise conclusions.

PART I.—DESCRIPTIVE

INTRODUCTION

The Technical Research Committee of the American Institute of Steel Construction by arrangement with the owners, architects, consulting engineer, and contractors for the Empire State Building equipped that building during its construction with instruments, by the use of which data were later obtained as to the effect of wind and the resulting stresses and strains.

With the exception of the work of Clyde T. Morris, M. Am. Soc. C. E., on the American Insurance Union Building[2] this is the first opportunity known to the writer in which engineers have been permitted to conduct an extensive study of the action of a large building over a period of several years, with a view to increasing their knowledge of the action of a structure subjected to wind loads. The data obtained, therefore, are of considerable value inasmuch as they tend to clarify the very intricate problem of determining the nature of wind pressure on large areas and permit the study of the plastic and elastic action of the building itself.

By the nature of the problem a high degree of accuracy was not necessary; nor was it obtainable. There were many factors beyond the control of the observers, and many data that were necessary for a complete solution of the problem could not be obtained. From the beginning of the project in April, 1931, until the removal of the instruments in the summer of 1936 a considerable number of observers gave their time to the task of making those records. Many of these data were fragmentary but as a whole they furnish a picture of the phenomena being observed.

DESCRIPTION OF BUILDING

The Empire State Building is the tallest in the world to date (1938); and it is not, like many tall buildings, simply a tower surmounting a comparatively low building. Its breadth is sufficient to present a very extensive surface to the wind (see Fig. 1). Its plan dimensions are 197.5 ft by 424.5 ft from the ground to the sixth floor. It has several setbacks, but from the thirtieth floor to the seventy-third, it covers approximately one-fourth the area of the ground floor. From the seventy-third floor it is gradually reduced in area to the roof on the eighty-sixth floor. A mast which supports the anemometer for measuring the wind velocity extends about 200 ft above the roof. All observations were made below the eighty-sixth floor. The design is almost ideally simple from a structural point of view. All the floors are symmetrical about two axes, with but few minor exceptions, which have little or no effect on the action of the building. The total height above the street floor, including the mast, is 1 248 ft.

FIG. 1.—SIDE VIEWS OF EMPIRE STATE BUILDING

Structurally, the building consists of steel columns and girders, the latter being fastened to the columns by the shallow wind-brace connections of the type shown in Fig. 2. In addition, the central bays around the elevator shafts have a system of knee-braces which extend from approximately the third point on the girder to the point where the corresponding girder on the floor below joins the column. The system of knee-braces in any set of bays between two columns, with the accompanying columns and floor-beams, forms a vertical truss which materially stiffens and strengthens the frame of the building. These are shown with their form of bracing in Fig. 3 which gives an outline of the frame of the building in the narrow direction. As explained in Part II, there are three typical frames in the narrow direction of the building.

The floors are of cinder concrete slab construction supported by steel beams approximately 8 ft apart. The outside partitions are covered with chrome-nickel steel and Indiana limestone. Until a floor was rented it had no interior partitions except those surrounding the elevators and utility rooms. Fig. 4 is a typical layout.

With the exception of one offset for the main entrance the columns are in rows in both directions and each column extends from the foundation to the roof. The symmetry and regularity of the building have aided greatly in the study of its action.

Surrounding the steel, and acting with it, are other materials of construction, such as concrete floors, tile and plaster partitions, etc. Much of this material is not elastic and does not follow Hooke's law. As a result, when it is subjected to loads, the building shows a predominance of plastic action; that is, when it is deflected by a horizontal force it will not return exactly to a definite fixed position. A study of the readings of the building deflections reveals this phenomenon clearly.

THE VICINITY

The buildings in the vicinity of the structure are low compared to those a few blocks farther north, where one group of the tall buildings of the city is located. The buildings along Forty-Second Street present a solid wall of high structures which tend to break up the air currents at elevations above, as well as below, their tops. There are a number of tall buildings to the west as well as to the north; and, to the south and the southeast, there are few obstructions. Fig. 5, a view of the city near the building, affords some idea of the character of obstructions which, it is easily seen, are of a type that would disturb the air currents and interfere with any tendency to be streamlined.

Fig. 6 is a map giving the approximate elevations, in feet, of the roofs of those buildings that are high enough, and close enough, to affect the air currents seriously. Fig. 7 gives the heights, in number of stories, of the buildings in the immediate neighborhood.

FIG. 4.—TYPICAL FLOOR LAYOUT. NUMBERS DENOTE OBSERVATION STATIONS

Several methods were used in making the survey for the maps in Figs. 6 and 7, after which the public records for the heights of the more important buildings were looked up as a check. Accuracy sufficient for the purpose was obtained by these methods although they could not be relied upon where great care was necessary. The first method used was to observe the heights with a hand-level from the several floors of the Empire State Building. This method proved inaccurate for all except the closest structures.

An ingenious method was suggested and used by one of the student observers, which proved quite successful. Photographs were taken from the seventy-fifth, fifty-fifth, and thirty-sixth floors using windows in the same vertical line. With the known distance between floors as a base the heights of the buildings could be computed from the photographs by triangulation. The distances to the buildings were known from the published maps so that checks on this work were obtained.

From Figs. 5, 6, and 7, it is quite evident that the structure is many times higher than most of its neighbors and even those that compare with it in height (more than one-half as high) are isolated towers a considerable distance away. The air currents at the lower elevations (to a height that is extremely problematical) are very much disturbed.

VELOCITY OF THE WIND

The velocity and direction of the wind were obtained from an anemometer installed approximately 15 ft above the top of the mast, or 1 263 ft above the street. This instrument relies for its operation on a 32-blade rotor which does not spin (as does the cup anemometer). The dial (not self-recording), was read just before and just after the deflection readings. The hands often fluctuated over a range of about 15 miles per hr during a severe storm. The average velocity was taken and not the maximum due to this swing. In one instance, a fluctuation of 20 miles per hr on each side of a mean of about 50 miles per hr was noted.

There is some question as to the accuracy of the anemometer for recording the velocity of the storm. Although the instrument may register, correctly, the velocity at the mast head at the time noted, the air currents are doubtless influenced by the presence of the building itself, as well as by the other tall buildings in the vicinity.

There are three Weather Bureaus on Manhattan Island, all within less than five miles of the Empire State Building. In order to have as many data as possible on the wind movement during the observations the records of these several Weather Bureaus were consulted. Table 1 gives the direction and velocity of the wind at each station, at the time of the observation indicated. In the case of the anemometer at the Empire State Building, the readings were taken as near as possible to the time of taking the other data and at the time indicated in Column (2). If the velocity needle was fluctuating the mean reading was taken. In the case of the three neighboring stations, the average velocity and direction during the hour of the readings were recorded. In addition, the maximum velocity for a 5-min period attained by the wind during

that same hour, as recorded by the Federal Observatory, is given in Column (11). The exact time that this maximum was taken is given in Column (12).

The maximum velocity during the storm of March 22, 1936, for a 5-min period, was 34 miles per hr in Central Park, and 65 miles per hr at the Federal Station. The extreme velocity at the Federal Station was 71 miles per hr whereas a velocity of 102 miles per hr was noted at the Empire State Building. A pressure of 20.2 lb per sq ft has been reached once in Central Park since 1919.

The Federal Observatory is in the Whitehall Building overlooking Battery Park on the south end of Manhattan Island. In the vicinity there are a number of buildings as tall or taller than the one containing the U. S. Weather

FIG. 7.—HEIGHT OF BUILDINGS IN IMMEDIATE VICINITY OF STRUCTURE; SHOWN IN TERMS OF NUMBER OF STORIES; NUMBERS IN CIRCLES ARE HEIGHTS, IN FEET

Bureau Station, which to a considerable extent affect the readings of the anemometer. These tall buildings lie to the north and the northeast. To the south and west there is nothing between the instruments and the harbor. The anemometer is 454 ft above the harbor, and about 4.5 miles due south of the Empire State Building.

The News Building is on the south side of Forty-Second Street between Second and Third Avenues, and about 900 ft east of Lexington Avenue. This structure is much taller than any other building east of Lexington Avenue, except the Chrysler Tower, so that all buildings that are anywhere near the anemometer in height are shown in Fig. 6. The height of the anemometer is 504 ft above the street and 30 ft above the roof.

The New York City Meteorological Station is in Central Park, about 0.3 mile west of Fifth Avenue and 2.9 miles north of the Empire State Building. The observatory is in the approximate center of the park which has a width of about 0.5 mile and a length of a little more than 2.5 miles. The anemometer is 62 ft above the ground and is of the rotary cup type. This elevation places it well above the trees of the park but lower than the buildings on the adjoining streets.

FIG. 9.—U-TUBE MANOMETERS

The direction and approximate velocity of the air currents around the Empire State Building have been observed by watching the drift of fog and of snow flakes. The results of one typical observation are given in Fig. 8 which shows that the flow of the air is greatly disturbed by the building in a manner that is far from simple. Another observation on February 8, 1936, showed definite vertical currents, up as well as down, whereas the anemometer recorded a zero reading and the direction arrow rotated in an irregular manner over the entire range of the dial.

During a strong wind a rubber balloon was tied to a long thread and sent out from the highest point of the mast. It did not move horizontally away from the wind as was expected, but eddied about the lee side of the building and the mast. It made one vertical trip the full length of the thread (several hundred feet) and returned. It did not leave the lee side of the building until 15 min after the thread was severed. From these observations it is quite evident that the velocity of the wind acting on the surface of a building is entirely too complicated to be represented by a single reading.

Table 1 shows that recording instruments within a few miles of each other differ widely in their readings while recording a storm. This table (which justifies considerable detailed study) reveals the fact that each station has individual characteristics that must be understood, when interpreting data.

MANOMETERS

In order to study the pressure and the pressure distribution of the wind over the surface of the building ten gages were placed on each of three floors: The thirty-sixth, the fifty-fifth, and the seventy-fifth (see Fig. 4).

The opening in the outside wall consisted of a hole, ¼ in. in diameter, placed on a spandrel of aluminum. Great care was taken in boring the hole to have the edges sharp and true. A 0.5-in. galvanized iron pipe, with specially designed air-tight couplings, led from each hole to one of two closets on this same floor. These pipes were embedded in the floor and the holes were bored during the erection of the building.

Each closet contained a rack consisting of ten glass tubes (see Fig. 9) which were fastened together in pairs at their lower ends by a short rubber tube, forming five U-tubes, which were partly filled with colored water. One end of each tube was connected to one of the galvanized pipes, previously described, by means of a rubber tube, thus subjecting it to the pressure of the outside air. The other end was open to the air pressure of the closet. Although the tubes were placed on a slant the scales were made to measure vertically; therefore, no allowance was made for this increase in length of tube. The difference in level between the two columns of water gave a measure of the difference in pressure of the air in the closet and that against the ¼-in. hole. There is some possibility that the air pressure in the two closets was not the the same during a high wind. The doors were left open during visual readings but not during the camera readings.

When the equipment was being installed it was felt that better information could be obtained by having all readings (on the manometers and on the steel) made at the same time by electrical control. In each closet a camera was focused on the five U-tubes; and each extensometer (described subsequently) had a camera attached to it. All were operated from a common button on the twenty-fourth floor. In its operation this set-up did not prove entirely satisfactory. During a strong wind storm the building not only deflects but also vibrates, and the camera may catch a reading on the steel at the maximum or minimum of the strain due to this vibration. With the manometers, on the other hand, the fact that the wind comes in gusts might cause a reading higher or lower than the mean pressure. The average was taken in all cases when visual readings were made. It took several minutes from the time the dial was read on the first floor until the observer had made all his readings on the several floors and returned to the first floor. In a considerable number of cases the character of the storm changed very materially during this time.

The cameras were a source of annoyance because they often jammed, and, in this way, much valuable information was lost.

In computing the pressures given in Table 2, 1 in. of difference in liquid elevation was taken as 5.2 lb per sq ft on the wall surface. The manometer readings given in Table 2 show the general character of the pressure distribution during a number of characteristic storms. Where the wind changed materially during a visual observation the results were not recorded. It is worthy of note that there is a great variation in the distribution of load among the floors. Some of the storms seem to affect only the upper floors and anemometers whereas others affect some lower level. One instance was noted in which the wind registered 70 miles per hr. Below the seventieth floor it was calm whereas above that floor the wind was strong. At another time a strong wind was noted at the thirty-sixth floor and it was comparatively calm at and above the fifty-fifth floor.

The manometer tubes (see Fig. 4) recorded both positive and negative pressures. Fig. 10 gives a graphic illustration of the distribution of the wind pressure over the surface of the building and impresses one with the lack of uniformity of this pressure. Three types of storms, as recorded by the anemometer, were selected.

Messrs. Hugh L. Dryden and G. C. Hill, of the National Bureau of Standards, subjected a model of the Empire State Building, 5 ft high, to air currents of known velocity in a wind tunnel, and recorded the pressure at a great number of points,[3] including the stations shown in Fig. 4. A comparison of the pressures on the model and those on the building shows clearly that the natural wind movements are not at all like those in a wind tunnel.

DEFLECTION

For a study of the deflection of a tall building under wind loads a better planned structure than the Empire State Building could not be found. It is not only the tallest building in the world but it is symmetrical in plan about both planes parallel to its sides, and through its vertical axis. The stair well, or fire tower, is near this central axis (Fig. 4) and gives a clear sight from the sixth to the eighty-sixth floor.

The data reported herein are those of the movement of the eighty-sixth floor relative to the sixth. The lateral movement of the sixth floor is doubtless small and may be neglected.

In effect, the building is a huge cantilever and as such has two distinct movements when acted upon by a wind storm: It deflects from the vertical; and it vibrates with a definite period, similar to the tines of a tuning-fork when struck. A steady wind causes deflections only, whereas a gusty wind will set up vibrations with amplitudes that vary with the strength and character of the storm. Under the action of a strong wind the building vibrates about a mean position in the direction parallel to its narrow side and, with a different period, in a perpendicular direction. Apparently, these two vibratory motions are independent of each other, differing both in amplitude and period.

Two methods were used to study the motion of the upper part of the building during a storm. A specially designed vertical collimator with a right-angle eye-piece was set up on the sixth floor and sighted on a target on the ceiling of the eighty-sixth floor. From a point near this target a plumb-bob was suspended so that the bob hung near the sixth floor. The collimator proved very useful in studying the vibrations of the building both as to period and amplitude; the plumb-bob was more useful in obtaining the deflections. At the time of reading either instrument the velocity and direction of the wind at the mast head were recorded.

THE FIRE TOWER

One of the most valuable features of the building from the standpoint of this investigation is the fire tower. Although there are several offsets in this tower there is a clear opening from the sixth floor to the eighty-sixth floor (a vertical distance of 972.5 ft) of about 54 in. in either direction, leaving sufficient room for both the plumb-bob string, and the collimator sight. In order to defeat the tendency for vertical currents of air to occur in the shaft, a diaphragm was installed at the fifty-fourth floor, holes being left for the line of sight and the plumb-bob string. Even after the installation of this diaphragm there is a strong current of air into the tower when the doors leading from the building floors are opened, particularly above the fifty-fifth floor. When the doors are closed the leakage of air under the door is quite perceptible but the volume of air admitted is small. At each floor the stairway is separated from the tower by a partition containing a door. All doors to the tower were kept closed except when in use.

---

[3] "Wind Pressure on a Model of the Empire State Building," by Hugh L. Dryden and G. H. Hill, *Research Paper No. 525*, National Bureau of Standards.

As the tower is very close to the vertical central axis of the building any rotation of the building about this axis does not affect the readings. Deflections that persisted over a considerable period of time could be obtained to any desired degree of accuracy by means of the plumb-bob, whereas rapid movements could be studied by means of the vertical collimator.

The Plumb-Bob

The plumb-bob consisted of a 35-lb concrete cylinder (Fig. 11) containing considerable scrap iron. It was suspended by a three-strand sounding cable from the ceiling of the eighty-sixth floor to a convenient height above the sixth floor so that the distance from the point of suspension to the center of the bob was 969.25 ft. Due to this great length of suspending wire the bob did not follow rapid movements of the building, but maintained a position under the mean location of its point of support.

The first bob designed had a brass point on the lower end but trouble was experienced by the weight bending this point when it hit the lower target (marked in tenths of an inch) on which the readings were made. In order to prevent this effect, and to allow for vertical adjustment, a very small bob was suspended from the lower end of the larger one. The point of this second bob was adjusted so that it exactly cleared the target.

Oil baths were used to damp out the swing of the bob. With the dampers the readings were easily obtained to within 0.1 in., or even closer, during a light wind. During a heavy wind the bob had a tendency to oscillate, due to the movement of the point of support and also to slight upward currents of air. As the motion in any definite direction was that of a damped harmonic it was not difficult to estimate the position of rest to within 0.2 in. and in most cases to within 0.1 in. Once or twice the position of rest was difficult to determine with an accuracy of less than 0.5 in. This occurred during very strong winds and was probably due to the shifting of the mean position of the eighty-sixth floor during the time the observations were being taken.

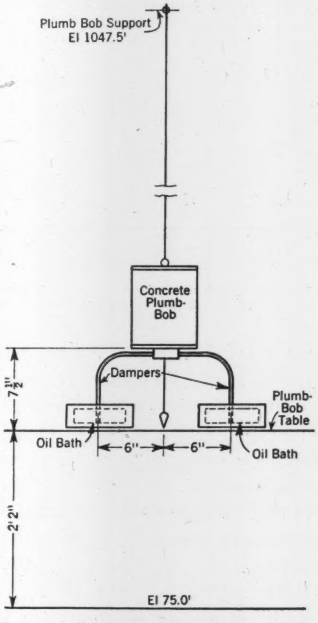

Fig. 11.—Diagram of Plumb-Bob Set-Up

Some question has been raised as to the accuracy of the plumb-bob as an instrument for noting the movement of the building because of the leakage of the air into the shaft and also because of the fact that the point of support is not steady. The size of the fire tower, except at the diaphragm across the fifty-fourth floor, is more than 125 sq ft, with the result that upward currents are slight and those that do occur do not deflect the plumb-bob string in one direction more than in another. When a door was opened a serious disturbance occurred, but it subsided at once when the cause was removed. As to the effect of vibration on the action of the bob, it is to be noted that the building vibrates from 6 to 8 times per min whereas the computed period of the bob is between 34 sec and 35 sec. As the bob did not record movements of its support that are not of greater duration than the period of its swing, the building vibrations are not recorded by the bob, but their mean position is determined by it.

The tidal effect on a pendulum of this length can easily be shown to be small enough to be neglected.

A large number of readings have been recorded to show the position of the plumb-bob, together with the recorded wind velocity and direction. A few representative data are given in Table 3. In plotting these readings the writer divided them into three groups for the sake of clearness: Table 3(*a*), for a wind velocity of less than 20 miles per hr; Table 3(*b*), for recorded wind velocities between 20 and 30 miles per hr; and Table 3(*c*), for a wind velocity greater than 30 miles per hr. Fig. 12 is an example of the form in which the data were plotted.

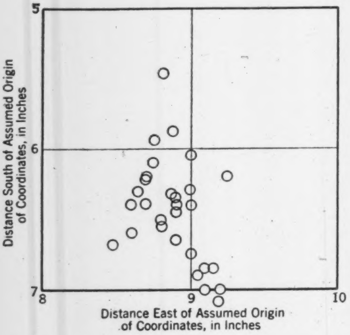

FIG. 12.—MOVEMENT OF PLUMB-BOB DURING A LIGHT WIND (0 TO 20 MILES PER HOUR)

The first group (see Table 3(*a*)) shows that the building fails to return to a definite position of rest. This is to be expected as there is considerable inelastic and semi-elastic material surrounding the steel frame. It is probable that this material resists recovery, and that there is a small amount of stress left in the steel after the building is relieved of a heavy wind pressure. As a result, if the wind were to shift to the opposite direction, the building would pass through the zero point of deflection much more readily than a simple stress-strain curve would indicate. This action would, in no way, endanger the building as the phenomenon will not occur except at low stresses. Fig. 12 gives an idea of the extent of this plastic set because it can be assumed that the deflection of the building due to the wind pressure is low and so may be neglected.

The forces due to the high wind (see Table 3(*c*)) are great enough to overcome the plastic deformations of the storm immediately preceding the one observed and so in each case, in the third group, the displacement would be due to the wind recorded and not to the effect of a previous storm.

† Month/day.

It is to be noted that the values in Table 3 do not indicate the maximum deflection of the building. They are only the mean position about which the building vibrates; for a maximum deflection one-half the amplitude of vibration should be added.

In order to make a further study of this plastic set in the narrow direction of the building, three sets of measurements were made to the plumb-bob string from reference points, on the several floors. As it required more than two hours for each set of readings it was necessary to make them during calm weather in order to be assured that the building did not shift during the time of the observations. These variations are plotted in the curves of Fig. 13.

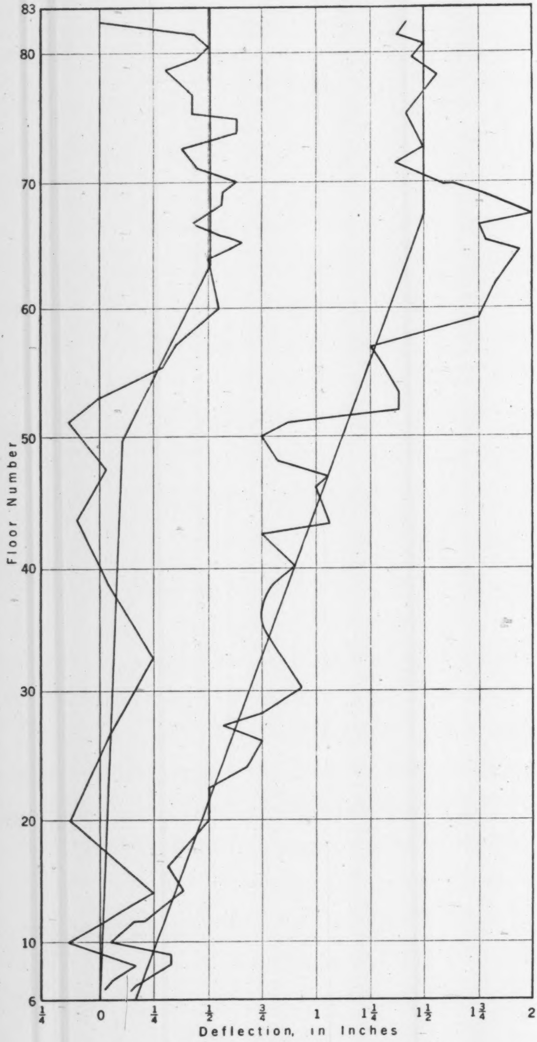

Fig. 13.—Check Measurements to Plumb-Bob String

Temperature Deflections

In order to ascertain the deflection due to the inequality of the temperature of the several sides of the building, observations were made throughout the day of August 24, 1936. The sky was clear and sunny, and the maximum temperature was 86° F at 3:00 P.M. There was little wind blowing, the anemometer reading from 25 to 30 miles per hr, with a steady wind from the west northwest. Table 4 gives the readings of the plumb-bob showing a north deflection of 0.25 in. at noon and an east deflection of 0.15 in. at 3:00 P.M. As the day was not cloudy, leaving the surface of the building exposed to the heat of the sun, it is inferred that the effect of temperature is only a minor factor in the results given in this paper.

The collimator was designed by the United States Coast and Geodetic Survey for the purpose of locating the reading points of triangulation survey marks above their permanent points. It consists essentially of a transit equipped with a right-angle eye-piece and a leveling bubble. The telescope has a focal length of about 8 in. One division of the leveling bubble represents 0.56 in. on the target; that is, the bubble has a sensitiveness of about 10″ of arc per division. The target can be read to 0.5 in.

As the principal value of the collimator lay in the study of the vibrations of the building it was used during high winds only. Hewitt Crosby, M. Am. Soc. C. E., reporting to the American Institute of Steel Construction,[4] stated that for some unknown reason the sixth floor tilted as much as four divisions of the dial, or approximately 40″ of arc. In light and steady winds the effect was eliminated by leveling the instrument carefully before taking a sight; but in strong or gusty winds, when readings must be made on a moving target, this was impossible. In extreme cases, the indicated error from this cause was found to be as much as 2 in. In strong winds, the motion of the target was irregular in direction, amplitude, and time.

Nevertheless, the instrument proved invaluable because it enabled one to study the movements of the top of the building qualitatively when acted upon by a high wind. Table 5 records the readings of the collimator, showing the amplitude of vibration of the building. A number of attempts were made to measure the deflection of other buildings by means of transits set up at a distance, but the writer knows of no case in which satisfactory results have been obtained.

† Month/day.

The period of vibration was observed by means of the collimator on November 1, 1932 (see Fig. 14). The north-south movement is given in Fig. 15.

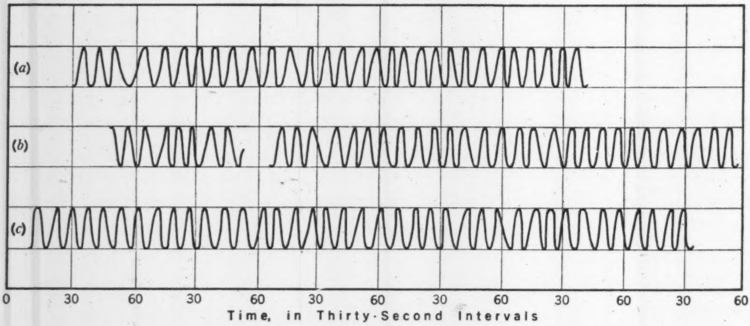

FIG. 14.—COLLIMATOR OBSERVATIONS ON THE SWING OF THE EMPIRE STATE BUILDING, NOVEMBER 1, 1932

The swing of one of the dials on the southwest corner column of the twenty-fourth floor (Fig. 4) was read on November 18, 1934. The curve thus obtained (see Fig. 15(*b*)) is the combination of two vibrations at right angles to each other, the north-south one dominating. The time of each high and low reading was taken and plotted. As the weight of the building was practically the same during these two observations the change of period from 8.28 sec to 8.14 sec is of considerable interest and is probably due to an adjustment of the several parts of the structure during severe storms.

EXTENSOMETERS

Four extensometers were attached to each of four columns on the twenty-fourth floor, by fastening an 0.001-in., Ames dial 8⅞ in. below the mid-height point. One end of a rod touches the stem of the dial, the other end being welded to the column 41⅛ in. above the midpoint of the column. In other words, the two points of attachment are 50 in. apart. They were all placed as near the outer end of the column flange (Carnegie H-beams) as possible.

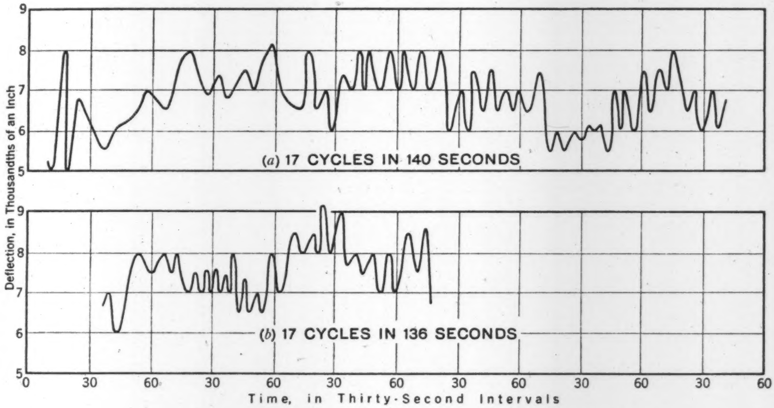

FIG. 15.—DEFLECTION OBSERVATIONS OF A CORNER COLUMN OF THE EMPIRE STATE BUILDING (TWENTY-FIFTH FLOOR)

With this arrangement the average of the differential readings of the dials gives the change of length of the column at its center line over a span of 50 in., thus furnishing a measure of the direct stress in the column. Although the angular change in the column can be computed it is not given herein because, unless the point of counterflexure is known, it is of little value.

The columns chosen for observation were the southwest corner column of the twenty-fifth floor and the three columns nearest to this corner. An offset in both directions places these columns in the interior on the twenty-fourth floor, thus facilitating the reading of the instruments.

Column (19) of Table 6 gives the sum of the readings of the several dials on the corner column in hundred-thousandths of an inch. Column (14) is the direct stress, in pounds per square inch, producing this strain. It is obtained by multiplying the strain by 29 000 000 and dividing by 50; or, the reading multiplied by 29 000 000 and divided by 50 × 100 000, or 5.8. In other words, the strain multiplied by the modulus of elasticity and divided by the length gives the stress, in pounds per square inch.

The stress in this same column due to the wind pressure has been computed from the manometer readings on the assumption that the building is a cantilever. The overturning moment of the wind about an elevation half-way between the twenty-fourth and the twenty-fifth floors has been computed for both a south

¶ Compass directions.

pressure and a west pressure. It is assumed: (1) That the pressure is uniform between the twenty-fourth floor and an elevation half-way between the pressure openings of the thirty-sixth and the fifty-fifth floors; (2) that it is also uniform between this elevation and half-way between the fifty-fifth and the seventy-fifth floors; and (3) that between this latter elevation and the top it is uniform. These several pressures are obtained for the south face by taking the readings of Tubes 2, 3, and 4, Fig. 4, subtracting the readings of Tubes 7, 8, and 9, and dividing the resultant by 3. These summations (before dividing by 3) for the several floors are given in Table 6, Columns (1), (3), and (5); similarly, for the west pressure points. The readings of Tubes 1 and 10 are subtracted from those of Tubes 5 and 6, and the result is divided by 2 (see Columns (2), (4), and (6), Table 6).

The moment about the central elevation of the twenty-fourth floor of a 1-lb pressure, uniformly distributed on the south face, has been computed to be: (*a*) For the thirty-sixth floor, 5 411 000 ft-lb; (*b*) for the fifty-fifth floor, 15 300 000 ft-lb; and (*c*) for the seventy-fifth floor, 35 400 000 ft-lb. Similarly, for the west face these values would be: (*a*) For the thirty-sixth floor, 3 900 000 ft-lb; (*b*) for the fifty-fifth floor, 11 100 000 ft-lb; and (*c*) for the seventy-fifth floor, 26 700 000 ft-lb. To obtain the total overturning moment in either direction one would multiply the sum of the manometer readings by 5.2 to reduce them to pounds per square foot, divide by two or three, and then multiply by the proper value. The effect of the six sets of readings is additive.

Resisting this is the column steel on the twenty-fourth floor. The beam formula, $s = \frac{M\,c}{I}$, is used to obtain the stress in the steel. This assumes that the planes of the twenty-fourth and twenty-fifth floors remain planes.

The value of I about each axis has been obtained by multiplying the area of each column, in inches, by the distance to the axis, squared, in feet. The reduction to inches is indicated by the factor, 12, which cancels out of the computations. The moment of inertia, I, about the east-west axis is $31\,454\,000 \times 12 \times 12$ in.^{4}, whereas, for the north-south axis, I is $70\,970\,000 \times 12 \times 12$. The corner column is 65.25 ft and 91.25 ft from the two axes.

To ascertain the stress in the corner column corresponding to the manometer readings on the thirty-sixth floor, north and south faces, the data from Column (1), Table 6, should be multiplied by $\frac{5\,411\,000 \times 12 \times 65.25 \times 12 \times 5.2}{31\,454\,000 \times 12 \times 12 \times 3}$; or, 19.45. Similarly, for the east and west faces:

$$\frac{3\,900\,000 \times 12 \times 91.25 \times 12 \times 5.2}{70\,970\,000 \times 12 \times 12 \times 2}\text{; or, } 13.05$$

For the fifty-fifth floor the corresponding values are 0.55 and 0.3695, whereas, for the seventy-fifth floor they are 1.272 and 0.895. Columns (7) to (12) of Table 6 are obtained from Columns (1) to (6) by multiplying by these several values. Column (13) is the algebraic sum of Columns (7) to (12) and is the computed stress in the column.

A comparison of Columns (13) and (14) shows the difference between the computed and the observed stresses in this corner column. It furnishes a rough check on the "cantilever method" of computing the stresses in the columns of buildings.

An assumed horizontal load of 20 lb per sq ft over the south face will give a computed stress of 2 330 lb per sq in. in this column, whereas the same pressure over the west face would give 1 070 lb per sq in.

PART II.—AN ESTIMATE OF THE STIFFENING EFFECT OF THE MASONRY

INTRODUCTION

Two assumptions are usually made in computing the stresses in the frames of tall buildings due to lateral forces when any of the so-called exact methods are used. One assumption is that the girders are rigidly connected to the columns and the other is that the frame is not braced by the walls, partitions, floors, and other parts of the building.

The first assumption has been given considerable study both in America[5] and in England.[6] Data have been collected and investigations are in process in some of the colleges of the United States to ascertain the percentages of error in the final results due to this assumption. It is hoped that, before long, the properties of the connections will be incorporated into the solution of the rigid frame subjected to lateral loads as a routine part of the solution.

The second assumption (neglecting the stiffening effect of the masonry) is of far greater influence but the writer has been able to find only meager reference on the subject. It is of more than academic interest, because the stresses in the frame are proportional to the deflection of the structure if the distribution of stress is the same when the masonry is present as it is in the steel frame acting alone. Therefore, the actual stress in the steel is reduced by the presence of the masonry in proportion to its influence on the stiffness. David A. Molitor,[7] M. Am. Soc. C. E., has given an estimate that the frame would be stiffened 30% to 50% if the connections were rigid. He has also estimated that the building is stiffened 300% to 400% by the materials other than the frame.

Rigidity is of considerable importance inasmuch as it affects the popularity of a building with tenants. If the structure is too limber the fact may be shown by cracks in the plaster and the movement may be noted in other ways causing lack of confidence in the safety of the structure. On the other hand, if it is too stiff the period of vibration will be short enough to be noticeable by the tenants, thus producing the same lack of confidence. In either case an unsatisfactory result is obtained. David C. Coyle,[8] M. Am. Soc. C. E., has published information on the period of vibration of a few existing structures and has collected considerable data. The problem will doubtless assume major proportions if office buildings are built higher in the future.

The capacity of a building to resist loads is not dependent upon the steel frame alone but upon the combination of steel and masonry, acting as a unit. As a large percentage of the material in the structure does not obey Hooke's law the stresses incurred at low loads may be of an entirely different character from those that would occur if the building were subjected to a dangerous wind pressure. It is doubtless true that, due to the greater stiffness and high elastic limit of the steel composing the frame, the stiffening effect of the masonry becomes less valuable as the loads increase. It is customary to ignore this source of strength, and probably wisely so, when designing a building; but it may account for the fact that few, if any, steel buildings have been destroyed by wind or earthquake.

An estimate of this stiffening effect should be of value, and, therefore, a study of some of the data taken from the Empire State Building investigation has been used to find the stiffening of this one building in the given range of working loads. The accuracy of the result is open to some question as it is based on only one set of computations and on data from only one building. A second set of computations has not been made because of the time and labor that is required to make the necessary model. However, this value gives a general idea of the ratio between the rigidity of a building without this bracing and one with it. For a building of different construction the ratio can be estimated with greater accuracy as a result of this study. The entire problem is one that does not allow for accurate work and great refinement; nor does it require it.

In evaluating the rigidity of the building, as actually constructed, advantage is taken of the fact that the period of vibration is a simple function of the rigidity. The building vibrates in the same manner as does the tine of a tuning fork; it is an elastic cantilever secured at its base and vibrated by the gusts of wind (not a steady force). The structure is composed of an elastic steel frame and of parts that are more or less plastic. This plasticity has a dampening effect on the vibrations but does not alter the period.

In order to form an estimate of the period of vibration, similar in all respects to the one observed but supported by the steel frame alone, a model was constructed and observed. It was constructed so that the principles of similitude could be applied, and the period of vibration computed, for a steel frame of the size of the building, and weighted to represent the dead load of the building.

From the period of vibration of the model and that of the building one can compute the relative stiffness of the model and that of the finished building. The one has rigid (soldered) connections and no masonry stiffening, whereas the other has riveted connections and a great mass of masonry surrounding the steel. The model represents the steel skeleton, proportionally weighted. It is assumed that the effect of the difference between the model and the building (masonry and connections) will be the same on the several floors of the structure.

The period of vibration does not depend upon the severity and the character of the horizontal loads but rather upon the several properties of the building that can be obtained from the engineers' plans, such as the weight, weight distribution, linear dimensions, and stiffness of steel members. Figs. 16 and 17 are views of the model used.

If two structures of the general nature of the one under consideration are built similar to each other, except for the scales of weight, length, modulus of elasticity, and moment of inertia of the sections, it can easily be shown that their periods when subjected to flexural vibration will vary directly as the weight and the cube of the length, and inversely as the modulus of elasticity and the moment of inertia of the members.

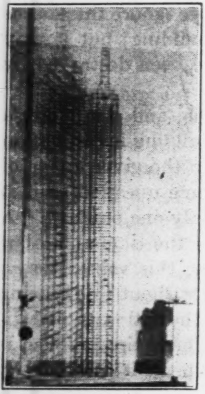

FIG. 16.—MODEL OF STRUCTURE

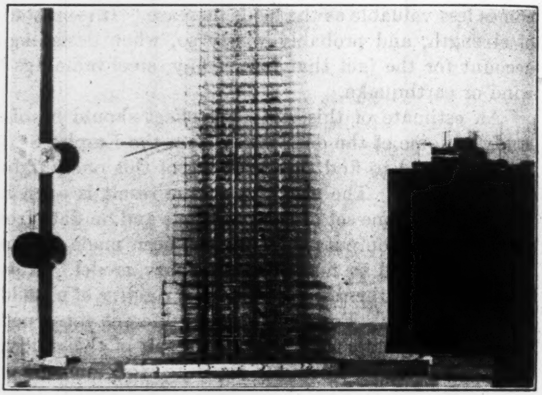

FIG. 17.—TESTING EQUIPMENT FOR MODEL

The period of vibration, expressed as a time dimension, T, or the ratio of homologous times, is expressed by the following equation,

$$T = \sqrt{\frac{W\,L^3}{E\,I}} \qquad \text{(1)}$$

in which W = the weight of the building or the model—or the ratio of homologous weights; L = the linear dimensions—or the ratio of homologous dimensions; E = modulus of elasticity—or the ratio of homologous elastic moduli; and I = the moment of inertia—or the ratio of homologous moments of inertia. Substituting known values in Equation (1),

$$T = \sqrt{\frac{50\,530\,000 \times 144^3}{2.07 \times 43\,000 \times 10^5}} = 130$$

The observed period of the model is forty-four vibrations in 6 sec; whence $\frac{6 \times 130}{44}$, or 17.8 sec, is the computed period of an unstiffened weighted frame. The building has an observed vibration period of about 8.25 sec (see Fig. 15). The ratio of these periods is then 8.25 to 17.8 or 1 to 2.16, which makes the stiffness ratio 2.16^2 to 1, or about 4.65 to 1. It can be concluded, therefore, that the structure is very close to four and one-half times as stiff as it would be if the steel frame alone held it in position.

Fig. 18(*a*) is the deformation curve of the model due to a pull at the eighty-sixth floor of sufficient magnitude to produce a unit deflection at that floor. The weight used was 5 lb, producing a deflection of 0.244 in. or 0.0488 in. per lb. Assuming similitude between the model and the building the force of the wind against the side of the structure can be estimated by the use of this curve and the deflection of the building. In computing the wind pressure its distribution must be assumed because a wind at an upper floor has more overturning effect than one lower down.

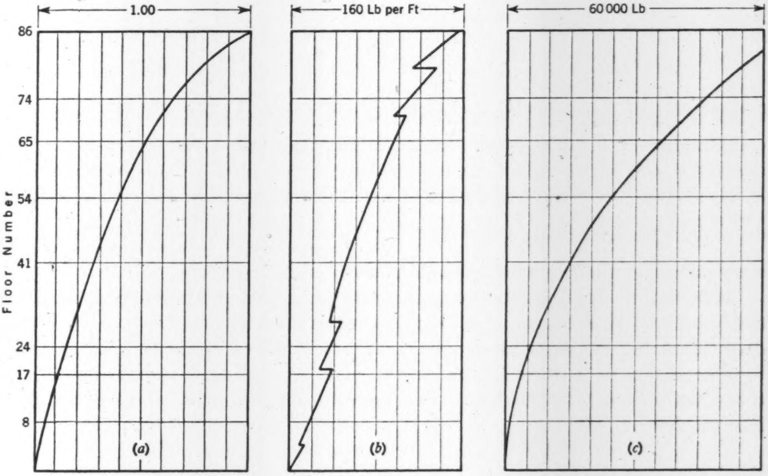

FIG. 18

The deflection due to a load at the end of a cantilever is given by the formula,

$$\Delta = K \frac{P L^3}{E I} \quad \text{.........................} (2)$$

in which K is an abstract constant depending upon the manner in which $E I$ varies along the length of the cantilever (the same in the model as in the prototype); that is, using ratios of similitude:

$$\Delta = \frac{P L^3}{E I} = P \frac{L^3}{E I} \quad \text{....................} (3)$$

in which Δ = the deflection; and P = a concentrated load. By Equation (1), $\frac{L^3}{E I} = \frac{T^2}{W}$; whence,

$$\Delta = \frac{P T^2}{W} \quad \text{........................} (4a)$$

and,

$$P = \frac{\Delta W}{T^2} \quad \text{........................} (4b)$$

In Fig. 18, if the ordinates of Fig. 18(*a*) are multiplied by the width of the building, the curve in Fig. 18(*b*) is obtained. In Fig. 18(*c*) is the integral of the curve of Fig. 18(*b*) obtained by plotting as ordinates the area below each point in Fig. 18(*b*). The total area of Fig. 18(*b*) is 64 600. Assuming a uniform pressure throughout the building of x lb per sq ft, and observing the deflection, the pressure is found to be as follows: From the plumb-bob readings in Table 3 the maximum south reading is found to be 9.76 in. and the minimum is 3.26 in. Assuming the difference is twice the deflection: $\Delta = 3.25$ in. The ratio of this deflection to that produced by a 1-lb load on the model is $\frac{3.25}{0.0488}$, or 66.6; the ratio of the times of vibration, T, is $\frac{8.25}{0.1385}$, or 59.6. The weight ratio has been computed as 50 530 000. Whence the horizontal pull at the eighty-sixth floor necessary to produce a deflection of 2.97 in. is $P = 66.6 \times 50\,530\,000 \times 59.6^2 = 11\,950\,000$ lb. From the curves of Fig. 18 the same deflection would be produced by a uniform load over the south face of: $\frac{11\,950\,000}{64\,600} = 18.5$ lb per sq ft, which includes the negative, as well as the positive, pressure.

It is to be noted that the foregoing data are based on the greatest recorded deflections. That storms producing greater deflections have occurred is doubtless true, so this value must be accepted with caution.

Conclusion 9, in Part III, is based partly on the values given herein and those of Column (14), Table 6. It is hoped discussion will bring out valuable information on this point.

Description of the Model

The steel frame of the Empire State Building lends itself readily to model analysis. It is unusually symmetrical and, with very few exceptions, the girders and columns can be reproduced as a rectangular grill with the columns extending from the foundation to the roof. The model was designed to have elastic properties similar to the frame when deflections in the narrow direction of the building (that is, parallel to Fifth Avenue) are being studied. It consisted of three grills fastened together in such a way that they were forced to vibrate as a unit. An examination of the plans shows that the frame at the foundation is composed of twenty-two rows of columns. The first eight rows consist of ten columns, the next six of nine columns and the last eight of ten columns. The twenty-two grills thus formed are forced to act as a unit by the concrete floors and other connections between them, and to vibrate with the same period. It was considered proper, therefore, to combine these grills into three, as indicated in Figs. 3, 16, and 17. In each grill the columns and girders were designed so they had a moment of inertia proportional to the sum of all eight (or six) corresponding columns or girders. At each floor the girders are secured to the columns by shallow wind-brace connections which, in this paper, have been considered as rigid. In addition, at certain joints, knee-braces extend from the intersection of a column and a girder to about the third-point on the girder in the floor above. These braces are represented in the model in their proper geometric relation by stiff brass wire (21-gage) which is a minimum allowable size for compression as a column.

In one or two cases, as at the Fifth Avenue entrance, there is a variation within the group of eight grills, which condition prevails only on the six lower floors. Another place where the building required more than three grills was between the seventy-second and the eighty-first floors, because the knee-braces did not lend themselves to a single pattern. In this case the model's grill is separated into two parts over this section of the structure; and so at these places the model contained five grills.

The distances from center to center of columns, and those between floors on the model, were laid out to a scale of 1 in. equals 12 ft, or a scale of 1 to 144. The grills were constructed of cold drawn brass 1/16 in. thick, which thickness was maintained for both girders and columns except in the case of some of the heavy columns in the lower part of the building where ⅛-in. material was used. The moments of inertia computed were divided by an arbitrary constant which was of such a value that the members of the model would be of a convenient size. These depths were calculated and the brass milled to the nearest thousandth of an inch. Each column was of one continuous piece, varying in depth to correspond with the computed value of its moment of inertia, whereas at each floor the girders were represented by a continuous member whose depth was changed at the points where it intersected the columns.

Each of the grills was formed by laying the girders on the columns and soldering them with soft solder. It was considered unwise to use hard solder for fear of drawing the temper in the brass.

The three grills were fastened together at approximately every eighth floor by means of horizontal trusses having no vertical stability but considerable lateral rigidity. Between the third, and also the eighth, sets of columns vertical trusses were placed between the two grills so that the model would have rigidity perpendicular to the direction of vibration. These trusses each consisted of a piece of cold drawn brass wire (21-gage) bent to form the webbing of a Warren truss whose chords were the columns. These trusses had no stiffening effect in the direction of vibration but acted as spacers between the grills, holding them about an inch apart. The posts were set in sockets in a steel frame, 4½ by 13/16 by 24 in., and doweled securely so that the rigidity of the base was as stable as the rock on which the building itself rests.

Representative specimens of the brass strips were tested, after milling to a depth of approximately that of an average beam, in order to find the value of E, the modulus of elasticity. This was done again after the strip was treated to considerable heat, which was applied in the same manner as was done in making the soldered joints. No change in modulus was noted.

Some trouble was experienced with the soldered joints flowing when subjected to a long continued stress. In order to determine whether these joints were strong enough to carry the stresses during the period of vibration (about 1/7 sec), the model shown in Fig. 19 was constructed. The joint at Point A was first made perfectly rigid by clamping the two pieces of brass together with a C-clamp which exerted enough pressure to prevent slippage. The lever was then vibrated and the period noted by the mark of a pen on a drum revolving

42.5 times per min. The clamp was removed and the joint soldered in the same manner as the joints in the model. The lever was again vibrated, and if the joint had not held satisfactorily, part of the motion would have gone through this joint into the section beyond and thus would have slowed down the period. The period of vibration used was approximately the same as that of the model, the weight being adjusted to produce it. Five readings over a fixed period of time showed, for the soldered joint: 27.5, 27.6, 27.6, 27.7, and 27.8 half vibrations, or a mean of 27.64. For the clamped joint, on the other hand, the readings were: 27.5, 27.8, 27.6, 27.8, and 27.6, with a mean of 27.66. The difference between the two means is low enough to warrant the conclusion that the soldered connection is satisfactory when the stress is low and of short duration.

FIG. 19

In making the model it was impracticable to control both the area and the moment of inertia of the several members as the constant width of 1/16 in. had to be maintained, that being the thickness of the brass ribbon used. The areas, therefore, are not proportional to those of the building. In the case of the girders the direct stress is low and so the lack of proportionality is not objectionable. With the columns, however, the direct stress and the areas do enter into the deflections of both building and model and thus introduce a small error into the results. The fact that the areas of the braces in the model are too large for similitude has little influence on the results.

The weight of each floor was obtained from the column schedule of the steel plans. The total weight of the building above each floor was obtained by adding the stresses in all columns on that floor. The increment for each floor was obtained from these data. The partition loads and live loads were subtracted where the floors were not occupied. In the case of the occupied floors an estimate was made of the added weight and the model vibrated under conditions both allowing for this added weight and omitting it. The difference was not noticeable.

These computed floor loads were divided by an arbitrary constant and the weights of the floors in the model were increased to the computed value by the addition of pieces of steel.

In computing the weight of the model the weight of the brass girders and columns was first computed and distributed at each floor. The weights of the knee-braces and the several stiffening trusses were obtained by observing the length of the wire used in making them. The model was then weighed and the difference between the computed and actual weight was taken as the weight of the solder. This was distributed among the several floors in proportion to the number of joints on that floor. To each floor was then added enough weight in the form of steel rods to bring its weight up to the proper ratio. In a few cases this added weight was computed to be negative, in which case one-half the value was subtracted from the weight to be added to the floor below and the other half from that to be added to the floor above. The weights were secured in position by means of rubber bands whose weight was also considered.

The model, as thus designed and constructed, was similar to the building in the following particulars:

(*a*) Its geometrical proportions (both vertically and in a direction parallel to its narrow face) were to a scale of 1 to 144;

(*b*) Its weight distribution was the same as that of the building, and its weight, or mass ratio, was 1 to 50 530 000;

(*c*) The ratio of modulus of elasticity of the materials used in the model to that of the steel frame of the building was 14 to 29; and,

(*d*) The ratio of the moments of inertia (and, therefore, the ratios of the stiffness of the various members of the model, to the corresponding members of the building) was 1 to $43\,000 \times 10^5$. This ratio was chosen because it produced sizes of members in the model with which it was practical to work.

The model was not similar to the building in the following particulars: (1) In the dimensions perpendicular to the narrow face of the building; (2) in the method of fastening girders to columns; (3) in the fact that it is not braced by masonry surrounding the frame—floors, walls, partitions, and other building materials; and, (4) in the cross-sectional areas of the several members.

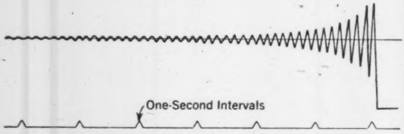
Fig. 17 shows the method of obtaining the vibration characteristics of the model. A 5-lb weight was used to produce the horizontal pull. The connection was broken suddenly by means of a trigger trip.

The horizontal movement was recorded by means of a thread attached to the model at one end and held taut by a rubber band at the other. A lever, holding a pen, was attached to the thread in such a manner that the pen traced the movements of the model on a revolving disk. A clock indicated the seconds on the disk. The lever exaggerated the movement of the model in the ratio of 478 to 240. Fig. 20 gives the curve produced with: (*a*) The load and recorder attached to the eighty-sixth floor; (*b*) the load on the eighty-sixth floor and the recorder on the sixty-fifth floor; and (*c*) the load on the sixty-fifth floor and the recorder on the eighty-sixth floor. The recorder was placed on the eighth, seventeenth, twenty-ninth, forty-fourth, fifty-fourth, sixty-fifth, seventy-fourth, and eighty-sixth floors. For each position the load was applied and suddenly released at all the floors named. Thus, a series of sixty-four curves similar to those of Fig. 20 were produced. The period of vibration was the same in all the curves.

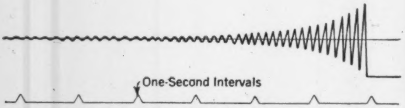
The curve of Fig. 18(*a*) was plotted from measurements taken from this series of curves. The position before and after releasing the 5-lb weight was used as the deflection due to the pull.

THEORY

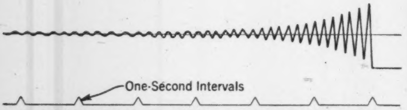
The derivation of the following formulas is given so that one may note the approximations involved in Equation (20) and thus estimate the errors if the result of neglecting them is open to question.



(*a*) LOAD AND RECORDER AT 86TH FLOOR



(*b*) LOAD ON THE 86TH FLOOR; RECORDER AT THE 65TH FLOOR



(*c*) LOAD ON THE 65TH FLOOR; RECORDER AT THE 86TH FLOOR

FIG. 20.—VIBRATION CURVES OF MODEL

Let A B in Fig. 21 represent a cantilever secured at Point A and vibrating about its neutral position, in a plane parallel to the paper, with a simple harmonic motion. This cantilever may be made up of a complicated set of springs, as girders and columns; or it may be a simple spring. A mass, $m\,dx$, is fixed at Point P, the symbol, m, being the mass per linear unit; it may be a function of x. When the particle, $m\,dx$, is in a position of maximum deflection the velocity is zero, and all energy is potential. This energy is stored up in the stressed fibers of the cantilever. If the cantilever is a building frame this energy is the internal energy of the strained columns and girders. When the particle, $m\,dx$, is in the neutral position all the energy is transferred to kinetic energy. If the period of vibration is T and the amplitude of vibration is y the velocity, v, at the central position is given by the equation,

$$v = \frac{2\pi y}{T} \quad \text{(5)}$$

The kinetic energy, W_k, of a moving mass is $\frac{m v^2}{2}$, and the energy in the mass is,

$$W_k = \left(\frac{m\,dx}{2}\right)\left(\frac{4\pi^2 y^2}{T^2}\right) = \frac{2\pi^2}{T^2} m y^2\,dx \quad \text{(6)}$$

in which both m and y are functions of x. In some cases it may be possible to express m as a mathematical function of x, but in any specific example the distribution of the mass over the length of the structure can be found. At the point of maximum deflection the acceleration of the mass, $m\,dx$, is equal to,

$$a = -\frac{4\pi^2 y}{T^2} \quad \text{(7)}$$

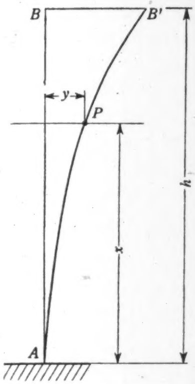


FIG. 21

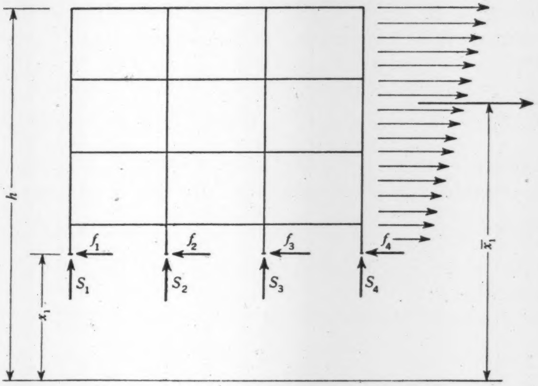

FIG. 22

and, since $f = m\,a$, the force exerted by, or on, Mass m, due to its acceleration, is,

$$df = -\frac{4\,\pi^2}{T^2}\,m\,y\,dx \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

This is the force that produces the stress throughout the cantilever and determines the value of y and, consequently, the shape of the curve of maximum amplitude. In addition to this energy of horizontal motion the point, P, will fall or rise a slight distance, b, producing a change in potential energy of $b\,g\,m\,dx$, which gives:

$$W_t = \frac{2\,\pi^2}{T^2}\int_0^h m\,y^2\,dx + g\int_0^h b\,m\,dx \ldots\ldots\ldots\ldots (9)$$

as the total energy which changes from kinetic to potential as the particle moves from the central position to the position of maximum amplitude. In Equation (9), $g =$ the acceleration due to gravity.

The second term in the problem considered in this paper is of minor significance and value, although in some cases, as a pendulum, it might be a dominating factor. Let Fig. 22 be that part of the frame forming the cantilever of Fig. 21, above which is a plane half-way between the nth and the $n + 1$ floor, or a distance, x, from the base. At maximum amplitude the structure is acted upon by the forces, F, shown in the diagram, in which,

$$F = \frac{4\,\pi^2}{T^2}\int_{x_1}^h m\,y\,dx \ldots\ldots\ldots\ldots\ldots\ldots (10a)$$

and the moment above Point C is,

$$F\,(\bar{x} - x_1) = \frac{4\,\pi^2}{T^2}\int_{x_1}^h m\,y\,x\,dx - F\,x_1 \ldots\ldots\ldots\ldots (10b)$$

Each column resists a fraction of the shear force, F, and a thrust, S, as well as a moment, M, which is not shown. The values of the forces (such as S) are assumed to be proportional to the moment about Point C as given by Equation (10*b*). The values of the column shears have a definite but unknown distribution among the columns and as their sum total is equal to F they are proportional to this value and may be represented by the fractional force, $\frac{p\,F}{q}$, in which p and q are abstract, dimensionless numbers. The values of S are probably approximately proportional to their distance from Point C. Let e be the distance from Point C to any given column and $\frac{c}{d}$ (a ratio of dimensionless abstract numbers) be the fraction that corrects for any lack of uniformity in the stress distribution. The value of Moment M is equal to the shear times the distance to the point of counterflexure or r, whence,

$$\Sigma\, S\, e = \frac{4\,\pi^2}{T^2} \int_{x_1}^{h} m\, x\, y\, dx - F\, x_1 \ldots\ldots\ldots\ldots\ldots (11a)$$

and,

$$S = \frac{1}{e}\frac{c}{d}\left[\frac{4\,\pi^2}{T^2} \int_{x_1}^{h} m\, x\, y\, dx - F\, x_1\right] \ldots\ldots\ldots\ldots (11b)$$

The energy in a column under an axial load, however, is equal to one-half the stress times the strain, or,

$$W_a = \frac{S}{2}\frac{S\,l}{A\,E} = \frac{S^2 l}{2\,A\,E} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12a)$$

or,

$$W_a = \frac{16\,\pi^4}{2\,T^4}\frac{1}{e^2}\left(\frac{c}{d}\right)^2 \frac{L}{A\,E}\left[\int_{x_1}^{h} m\, x\, y\, dx - x_1 \int_{x_1}^{h} m\, y\, dx\right] \ldots (12b)$$

The shear on the post is,

$$V = \frac{4\,\pi^2}{T^2}\frac{p}{q}\int_{x_1}^{h} m\, y\, dx \ldots\ldots\ldots\ldots\ldots\ldots\ldots (13a)$$

and the moment in the column at any point is,

$$M_c = \frac{4\,\pi^2}{T^2}\frac{p}{q}\, r \int_{x_1}^{h} m\, y\, dx = \frac{j\, r}{T^2}\int_{x_1}^{h} m\, y\, dx \ldots\ldots\ldots\ldots (13b)$$

if $4\,\pi^2 \frac{p}{q} = j$, a substitution constant. The moment at the end of a girder is proportional to the moment in the column adjacent to that end, plus the difference in the thrusts, S, on this column above and below the joint, times the distance from the joint to the point of counterflexure in the girder:

$$M_b = M_c \frac{u}{v} + (S_n - S_{n+1})\, 0 \ldots\ldots\ldots\ldots\ldots\ldots (14a)$$

but, since $S_n - S_{n+1}$ is proportional to F:

$$M_B = \frac{u}{v} \times \frac{4\,\pi^2}{T^2} \times \frac{p}{q}\, r \int_{x_1}^{h} m\, y\, dx + \frac{i}{n} 0 \frac{4\,\pi^2}{T^2} \int_{x_1}^{h} m\, y\, dx$$

$$= \frac{K\, r}{T^2}\left[\int_{x_1}^{h} m\, y\, dx\right] \ldots\ldots\ldots\ldots\ldots\ldots\ldots (14b)$$

in which $K = \frac{u}{v}\frac{p}{q} + \frac{i}{n}\frac{o}{r}$ is an abstract number; but the energy in the beam or column due to bending is equal to, $W = \int_0^l \frac{M^2\,dx}{2\,E\,I} = \frac{1}{2\,E\,I}\int_0^l M^2\,dx$, in which l is the length of the member. Substituting the values:

$$M_c = j\,r \int_{x_1}^{h} m\,y\,dx \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15a)$$

and,

$$M_b = \frac{K\,r}{T^2}\int_{x_1}^{h} m\,y\,dx \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15b)$$

the energy in the column is expressed by:

$$W_c = \frac{j^2}{2\,E\,I\,T^4}\left[\int_{x_1}^{h} m\,y\,dx\right]\left[\int_0^l r^2\,dx\right] \ldots\ldots\ldots\ldots (16a)$$

and, the energy in the beam, by:

$$W_b = \frac{K^2}{2\,E\,I\,T^4}\left[\int_{x_1}^{h} m\,y\,dx\right]\left[\int_c^l r^2\,dx\right] \ldots\ldots\ldots\ldots (16b)$$

the second integral in each case being taken from the point of counterflexure to either end of the beam or column. Collecting these terms and equating the energy of motion given by Equation (9) against that of the stored energy of the deflected structure:

$$\begin{aligned} &\frac{2\,\pi^2}{T^2}\int_0^h m\,y\,dx + g\int_0^h b\,m\,dx \\ &= \frac{16\,\pi^4}{2\,T^4}\sum\frac{1}{e^2}\left(\frac{c}{d}\right)^2\frac{L}{A\,E}\left[\int_{x_1}^{h} m\,x\,y\,dx - x_1\int_{x_1}^{h} m\,y\,dx\right]^2 \\ &\quad + \frac{1}{2\,T^4}\sum\frac{j^2}{E\,I}\left[\int_{x_1}^{h} m\,y\,dx\right]^2\left[\int_c^l r^2\,dx\right] \\ &\quad + \frac{1}{2\,T^4}\sum\frac{K^2}{E\,I}\left[\int_{x_1}^{h} m\,y\,dx\right]^2\left[\int_0^l r^2\,dx\right]_x \ldots\ldots\ldots\ldots (17)\end{aligned}$$

Using capital letters for the dimensionless terms, which are, therefore, independent of the character of the model and its relationship to its prototype, Equation (17) becomes (after multiplying by T^4):

$$\begin{aligned} &T^2\,A\int_0^h m\,y^2\,dx + T^4\,B\,g\int_0^h m\,b\,dx = C\sum\frac{l}{e^2\,A\,E}\left[\int_{x_1}^{h} m\,x\,y\,dx\right. \\ &\quad \left. - x_1\int_{x_1}^{h} m\,y\,dx\right]^2 + D\sum\frac{r^3}{E\,I}\left[\int_{x_1}^{h} m\,y\,dx\right]^2 \\ &\quad + F\sum\frac{r^3}{E\,I}\left[\int_{x_1}^{h} m\,y\,dx\right]^2 \ldots\ldots\ldots\ldots\ldots (18)\end{aligned}$$

in which A, B, C, D, and F are abstract numbers in the terms representing the energy: (a) Of motion of the mass of the structure; (b) of position of the mass of the structure; (c) in the columns due to direct thrust; (d) in the columns due to bending; and (f) in the beams due to bending. Neglecting the second term as small, and the third term as being probably small:

$$T^2 = \frac{D \sum \frac{r^3}{E\,I} \left[\int_{x_1}^{h} m\, y\, dx \right]^2 + F \sum \frac{r^3}{E\,I} \left[\int_{x_1}^{h} m\, y\, dx \right]^2}{A \int_{0}^{h} m\, y^2\, dx} \quad \ldots\ldots (19)$$

Writing the dimensions of these terms for similitude:

$$T^2 = \frac{\frac{L^3}{E\,I} \left[\frac{M\,L^2}{L} \right]^2}{\frac{M\,L^3}{L}} = \frac{M\,L^3}{E\,I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (20)$$

that is, the square of the period of vibration of the frame varies directly as the mass and the cube of the linear dimension and inversely as the modulus of the material and of the moments of inertia of the members. As the mass ratio is the same as the weight ratio the formula is the same as Equation (1).

PART III.—CONCLUSIONS

The following conclusions have been suggested by the data recorded in this paper:

(1) The distribution of the wind pressure on a tall building is very complicated and irregular, the air currents having been broken up by the surrounding structures and by the building itself.

(2) The action of a building under horizontal loads is plastic as well as elastic, with the result that strains and deflections are not proportional to the forces that produce them.

(3) The manometer readings do not give a true picture of the forces acting on the building, but do give the pressure at definite isolated points. This is because the wind comes in gusts that affect only a small surface. Frictional resistance has some influence.

(4) The deflection of the building due to the sun shining on one side of it (and expanding that side) is practically negligible.

(5) The horizontal deflection of this building during a wind storm is notable because of its popular interest and the small amount of data on this subject.

(6) Theoretically, there is danger of designing a building too stiff as well as not sufficiently rigid.

(7) The cantilever and portal methods of design have neither been corroborated or refuted by these data.

(8) The masonry increases the rigidity of the building about 350% more than that of the unsupported frame.

(9) The data herein given have not shown that 20 lb per sq ft is an improper value for the assumed lateral load on a building of the type of the one investigated when in a similar environment. This leaves the masonry as an added, but not perfectly reliable, factor of safety.

ACKNOWLEDGMENTS

The design and installation of the instruments herein described were made by the engineering staff of the American Institute of Steel Construction. The firm of Shreve, Lamb and Harmon, architects of the building, co-operated in the installation of the instruments and the gathering of the data. Many data and many suggestions were furnished and made by the late H. G. Balcom, M. Am. Soc. C. E., a member of the Institute's Committee on Research and Engineer of the design and construction of the building. F. H. Frankland, M. Am. Soc. C. E., member of the Committee and Chief Engineer of the Institute, supervised the design and installation of the manometers, extensometers, and cameras, and the collection of the first set of data (including that for the area shown in Fig. 7). Mr. Hewitt Crosby obtained some of the collimator data and assisted in obtaining some of the other readings. Alfred F. Samuel, Jr., Assoc. M. Am. Soc. C. E., installed the collimator target and made many of the readings. The second group of readings (the vicinity map of Fig. 6), the deflection curves, and Weather Bureau reports were obtained by the writer assisted by Walter J. Gray, Jun. Am. Soc. C. E., and other students from the College of the City of New York, in New York City. The model was made by the writer in the laboratories of the City College. The curves and readings from the model were made by Mr. Arthur Gatterdam. The balloon experiment was made, and many helpful suggestions were given during the first period of the research by Mr. Coyle.

DISCUSSION

David Cushman Coyle,[9] M. Am. Soc. C. E. (by letter).—In the design of slender towers to be occupied by paying tenants, the proper criterion is not so much strength against being blown down as a feeling of solidity noted by the tenants during high winds. Few cases will be found in which the requirements of sensation do not give a tower of a highly conservative design as to strength.

The theory advanced by H. V. Spurr,[10] M. Am. Soc. C. E., is adaptable to a sensation criterion, since it involves forcing the floors to remain plane, thus facilitating the mathematics of cantilever vibration analysis, and since it also involves as an arbitrary constant the allowable static deflection.

For the purpose of analysis for sensation, the writer would modify the (wholly nominal) assumed wind load used by Mr. Spurr. Instead of 0 at the street line and 30 lb at the top, the writer would use 0.03 h lb at the top, which is 30 lb at Elevation 1 000.

There are two assumed constants to be used in the proposed modification of the Spurr theory, both of which may be refined by research. One is the absolute allowable wind loading, a value to be used in checking the design to guard against overturning. Professor Rathbun points the way to a method of evaluating this constant. Obviously, it is not a real pressure per square foot, evenly distributed over the building; nor does it have a relation to anemometer readings that can be discovered by logical analysis. However, if a series of readings of static deflection can be obtained and correlated with anemometer readings, and if the stiffness of the towers thus treated is known, it is obviously possible to obtain a nominal wind load varying from 0 at the bottom to $f(a)\ h$ at the top, that would produce, theoretically, the observed deflection ($f(a)$ is a function of the anemometer reading).

The stiffness of existing towers must be measured in order to analyze the foregoing factors. Generally, the designer must deal with irregular spacings of columns, offsets, and other anomalies. The mathematical treatment of this problem was published by the writer in 1932.[11]

Using the observed period of vibration, and the estimated actual dead and live loads, the actual stiffness can be determined and expressed in assumed nominal wind load per inch of static deflection. This is a different kind of quantity from the wind load previously mentioned. That is, a maximum wind load of some kind will be imposed by Nature, and the only question in this regard is to find a nominal load which, when applied to the analytical formula, will result in a tower that will stand up. On the other hand, the stiffness is an intrinsic quality of the building definable as a ratio between load and deflection, and has no concern with whether a load of that form or size could ever exist in Nature.

Thus, by knowing the period of vibration—easily observed with a seismograph—and the weights, the true over-all stiffness of towers (including effects of steel and masonry) is easily found. Using this known stiffness, it will be possible, at considerable expense for research, to find, roughly, the proper absolute nominal wind load for design of stability.

[10] "Wind Bracing," by H. V. Spurr, McGraw-Hill, 1930.

[11] "Stiffness of Sky-Scrapers," International Assoc. for Bridge and Structural Eng., Paris, France, May, 1932.

Thereafter, a maximum hurricane of any specified velocity could be assumed as measured by the anemometer, and the wind diagram to be used in checking for over-turning could be derived therefrom.

There remains the problem of securing the proper stiffness for comfort. To obtain an analytical description of the criterion for comfort it is necessary to know, first, the form of the function of period and amplitude that corresponds to sensation. This function has been commonly assumed to be acceleration, which, since amplitude is proportional to static deflection, is described by the ratio, $\frac{y}{T^2}$, y being the deflection and T, the vibration period. The conclusion reached by Mallock that there has been some experimental work indicating vibration reaches the threshold of sensation at an acceleration of 1% of g. The vibrations involved, however, were tremors of the order of 5 to 25 per sec; the results, therefore, do not apply to wind sway. The writer has felt vibrations of an amplitude of about 0.5 in. at 13 per min, which gave an acceleration of only about 0.25% of g. It seems that the feeling of slow sway is different in kind from the feeling of tremor. It is possible that tremor may be a muscle or skin sensation, whereas sway may be a sensation of the semi-circular canals.

Another seeming fact throws light on this question. If a tower of given size and weight were to be made twice as stiff by the addition of extra bracing, the acceleration would not be changed because the amplitude would be cut in two and the period would be divided by $\sqrt{2}$, leaving $\frac{y}{T^2}$ unchanged. Adding stiffness to a tower without changing the weight, therefore, does not improve its acceleration; yet it seems fairly clear from observation that the stiffer tower is the more comfortable.

If the function is not $\frac{y}{T^2}$, it seems necessary to make tests on a shaking-table in a psychological laboratory to find out what the function is. The next step would be to measure a large number of towers for T and y, by means of the seismograph for T and analysis using the weights so as to find y. Then, using the necessary function of T and y, these towers may be arranged in statistical order, from the worst to the best. By observing this array one can then pick the desired flexibility or stiffness to correspond with the quality of building desired. Thus, a tower can be planned so that its amplitude and period are in a class with the Woolworth Building or the Metropolitan Life Building (both in New York City), or, on the other hand, one may design with just sufficient strength to pass inspection, according to the proposed use and the character of the job. Buildings to be used for sleeping should naturally be steadier than an office building needs to be. Note that amplitude can be reduced by additional bracing, but only with a corresponding increase in speed of vibration. Speed, however, can be reduced without changing the amplitude, by adding weight at the top. The architect's ideal of a "tin tower," made of light weight materials, is, therefore, not consistent with comfort, above a very limited ratio of slenderness.

The lines of research sketched herein would require considerable time and money, but if a new skyscraper era were to occur, with higher and more slender towers, such research, continuing the valuable pioneer work reported by Professor Rathbun, seems necessary to obtain a rational method of design for the major factor of commercial success—the occupants' feeling of security.

CLYDE T. MORRIS,[13] M. AM. SOC. C. E. (by letter).—The fact that so little has been published giving observed data on the stresses and deformations produced in actual buildings by the wind, makes this paper especially valuable, even though definite conclusions and recommendations cannot be drawn from these data.

The observations of the air currents surrounding the building and of the variation of the pressure recorded on the manometers show the futility of extreme refinements in the mathematical calculation of wind stresses. This does not mean, however, that the elastic theory of stress distribution may be discarded, but only that the basic values of the wind pressure used may be in error.

From the observed deflections of the building Professor Rathbun computes the equivalent uniform wind pressure to have been 13.4 lb per sq ft at a wind velocity of about 60 miles per hr (see following Equations (4)). If it is assumed that the pressure increases as the square of the velocity an equivalent pressure of 20 lb per sq ft would be caused by a wind velocity of about 73 miles per hr which would indicate that the usual assumption of 20 lb per sq ft being taken entirely by the steel frame is not too conservative. Conclusion (8), that the masonry increases the rigidity of the building about 350% more than that of the unsupported frame, must not be construed to mean that the masonry increases the load-carrying capacity by that amount.

ROBINS FLEMING,[14] ESQ. (by letter).—The forces treated in this paper are determined by actual measurement from observations extended over a period of five years. A wealth of data is given such as can be found nowhere else. It is a matter of congratulation to the structural engineering fraternity that the owners of the Empire State Building made it possible that such observations could be made. It is fortunate that so able a presentation of these observations as that given in the paper under discussion is available.

Professor Rathbun states that Table 1 justifies considerable detailed study. This is true not only of Table 1, but of the entire paper. Surprising varying wind velocities at near-by points are shown in Table 1. More striking still are the variations of pressure at different heights of the same building, as indicated in Table 2. This raises the question as to the allowable wind pressure that should be assumed in the design of a tall building. How shall it be distributed? Referring to the pressure obtained by Messrs. Dryden and Hill[3] from a model of the Empire State Building placed in a wind tunnel, the author writes: "A comparison of the pressures on the model and those on the building shows clearly that the natural wind movements are not at all like those in a wind tunnel." This is a striking sentence. How far-reaching is its application? Incidentally, a writer on this subject has stated[15] of a transmission tower in Belgium, erected for purposes of observation, that: "The installation will enable the relation between the aerodynamic coefficients of a model and a full-sized tower to be established, and will also enable work to be carried out as to the frequency of gusts."

---

[13] Prof., Civ. Eng., Ohio State Univ., Columbus, Ohio.

[14] Civ. Engr. (*Retired*), New York, N. Y.

Table 3, reporting the plumb-bob observations, is important. The writer notes that Professor Rathbun gives the maximum deflection of the eighty-sixth floor relative to the sixth floor (a distance of 974 ft), as 2.97 in. (see text following Equations (4)). The casual reader may have difficulty in reconciling this deflection with the sentences of ten pages previous (see heading "The Plumb-Bob") that:

> "It is to be noted that the values in Table 3 do not indicate the maximum deflection of the building. They are only the mean position about which the building vibrates; for a maximum deflection one-half the amplitude of vibration should be added."

A few lines, or a page, could profitably have been added to the paper on this subject. The terms, "sway," "vibration," and "deflection," should be clearly defined. Where is the origin of co-ordinates taken?

In Table 5, the greatest amplitude of vibration recorded is from 0.5 to 5.2 in. in a north and south direction. The deflection, therefore, is $(5.2 - 0.5) \div 2 = 2.35$ in.

At this point attention is called to an opinion expressed[16] by Henry V. Spurr, M. Am. Soc. C. E. For a tower building 100 ft, center to center, of wall columns and 1 000 ft high, Mr. Spurr believes that a reasonable "yardstick" for a total deflection at the top is $0.001\,h$ "which is about $\frac{1}{8}$ in. per story." The question may be raised: Will such a deflection give sufficient rigidity?

The literature of deflections is extremely meager. Few measurements have been made; or if they have been made they have not been published. Observations[17] made on two buildings in Chicago, Ill.—the 17-story Monadnock Block and the 14-story Pontiac Building—were reported in 1894:

> "At the Monadnock Block the deflection was first observed by transits set in sheltered positions at points north and south of the north and south ends of the building and these observations were checked by observing the oscillation of plumb bobs suspended in the stairway shaft from the 16th floor. These two observations agreed very closely and show the vibration east and west from $\frac{1}{2}$ in. to $\frac{1}{4}$ in."

It should be said that the dead weight of the Monadnock Block would now be called excessive. This was the last skyscraper built with structural masonry walls. "The observations made on the Pontiac Building agreed quite closely with those on the Monadnock Block." No details are given. "The wind registered a little over 80 miles per hour."

[16] "Wind Bracing," by Henry V. Spurr, 1930, p. 27.

[17] *Engineering News*, March 1, 1894.

In a monograph,[18] published in 1912, Cyrus A. Melick, M. Am. Soc. C. E., records measurements of the vibration of a bent in a 17-story building. The greatest indicated wind vibration was 1 in. in a period of about 4 sec. It will be remembered that the distance traveled during a vibration is twice the deflection from a normal position.

The invariable practice in the design of steel-frame tier buildings has been to proportion the steel frame to carry the entire wind load to the column bases. Professor Morris[19] has stated that: "The stiffening effects of walls, partitions and floors should be neglected in calculating wind stresses. The entire wind load should be regarded as carried by the steel frame." The deflection calculated from the steel frame alone carrying wind pressure is much larger than the actual deflection. Mr. Molitor[7] computes the deflection of a 40-story building bent for a wind pressure of 15 lb per sq ft, to be 6.5 in. He adds a sentence, "If such a building in its completed state was to vary as much as 1 in. in the wind it might border on financial failure from the standpoint of occupancy."

The writer has calculated the deflection of the 20-story steel frame analyzed[20] by Wilbur M. Wilson and George A. Maney, Members, Am. Soc. C. E., in 1915, and found the deflection of the tops of the outer columns to be 3.91 in. This deflection was determined from Mohr's work equation, evaluating the integrals by a substitution formula given by Mr. Molitor.[21]

The process of calculating deflections in a multi-storied frame is long and tedious. For the Empire State Building it would be impracticable. Still, by an ingenious and elaborate method, Professor Rathbun arrives at the conclusion "that the structure is very close to four and one-half times as stiff as it would be if the steel frame alone held it in position" (see following Equation (1)).

The reason for the small observed deflections is discussed in Part II of the paper (under the heading, "Introduction"): "The capacity of a building to resist loads is not dependent upon the steel frame alone but upon the combination of steel and masonry as a unit." Mr. Molitor does not question any conclusions based on the theory of analysis as applied to a strictly engineering structure. "However," he writes,[22] "a steel building may be classed as an engineering structure only when the frame is bare; but when clothed with architectural coverings of concrete, stone and brick, with steel and concrete floors, tile partitions, etc., it becomes a composite structure, the nature of which cannot be appraised in terms of mathematics."

Mr. Jacob J. Creskoff[23] thinks that the present practice of restricting wind stresses to the steel frame is contrary to common sense: "A building resembles its frame only remotely, for the reason that the deflections of the horizontal members of the frame are limited by the slabs, and those of the vertical members are limited by the walls." He presents a "dynamic approach to design."

The "vertical beams" are considered to be composed of reinforced concrete and structural steel.

Significant sentences in the paper by Professor Rathbun are: "Rigidity is of considerable importance inasmuch as it affects the popularity of a building with tenants. If the structure is too limber, the fact may be shown by cracks in the plaster and the movement may be noted in other ways causing lack of confidence in the safety of the structure. On the other hand, if it is too stiff the period of vibration will be short enough to be noticeable by the tenants, thus producing the same lack of confidence" (see heading "Introduction" in Part II). The period of vibration is a function of the rigidity. Mr. Coyle believes that the necessity for stiffness depends on the occupancy. In 1929 he wrote[24]:

> "The relation between type of occupancy and sensitiveness to motion is a very important one. In an office the occupants are awake, clothed, occupied and expected to be paid for their time. It is daylight and there are other people about to give a sense of security. In an apartment house one may find himself alone, in bed, and in the dark, with a storm howling outside. Moreover, if one is ever subject to disturbance of the organs of equilibrium, such a condition is most apt to recur after an evening. Such being the case it is inevitable that some of the tenants in an apartment tower will feel or imagine strange things, and tell them to their friends."

The writer recalls an instance where the scream of a girl in a dance hall led to the hall being closed. An investigation was ordered and the details of the steel frame were found to be reprehensible. The owners of the building were put to a heavy expense before the hall was allowed to be re-opened. Mr. Coyle thinks that safety and the approval of the Building Department are not all that need be considered in the design of a tall building; "there is also required a technique in dealing with the cause and cure of imaginary feelings on the part of the tenant."[25]

Of the nine "Conclusions" in the paper the writer is specially interested in Conclusion (7): "The cantilever and portal methods of design have neither been corroborated nor refuted by these data." Both these conventional methods have been severely criticized. Messrs. Wilson and Maney[20] pronounce the "portal" method so inaccurate that it should never be used; and declare that the "cantilever" method is "quite accurate in some cases but may give results that are seriously in error." A slope deflection is presented which they consider "very accurate." A shorter approximate method is then proposed. As previously mentioned the writer calculated the deflection of the steel frame from the data given in the text to be 3.91 in. In an apartment house such a deflection would certainly affect rental receipts.

The Third and Final Report of the British Steel Structures Research Committee—a volume of 599 pages—was published in 1936. The conventional methods of obtaining wind stresses, "such as the Portal and Cantilever methods," are condemned in this report, which also states that the steel frame is not alone in resisting wind forces. The "architectural clothing" has a share; and,

[24] "Mushroom Skyscrapers," by David C. Coyle, M. Am. Soc. C. E., *The American Architect*, Vol. CXXXV, p. 289, June 20, 1929.

[25] "Testing the Strength of Skyscrapers," by David C. Coyle, M. Am. Soc. C. E., *Record and Guide*, Vol. 127, February 7, 1931, p. 12.

> "Floors are not the only clothing likely to affect the stresses in the steel framework. The fire-resisting stanchions and the external walls will play their part. * * * These tests have shown that the effect of clothing cannot be ignored. * * * In a large class of steel-framed buildings the floors and walls in conjunction so brace the framework that appreciable sway due to wind is prevented and the steel work is thus relieved of the responsibility of resisting wind shear."

In view of the foregoing and similar statements it is pertinent to ask why the conventional methods of obtaining wind stresses do not give ample security. Are they not as nearly correct as the elaborate and sometimes impractical methods that have been proposed? Mr. R. Gray, a British engineer, in a paper, "Wind Stresses in Tall Buildings,"[26] gives three methods for obtaining moments, shears, and thrusts, of which the "cantilever" and the "portal" are the second and third. Professor Rathbun considers that proposed methods of obtaining so-called "exact" results are unworkable except in the simplest cases. "Moreover," he states, "it is doubtful whether they are much nearer the truth than the results given by the common methods, since the influence of the walls and floors, though quite considerable, is quite incalculable."

In connection with Conclusion (9), it is interesting to note that the horizontal pull at the eighty-sixth floor, necessary to produce a deflection of 2.97 in., is equivalent to that produced by a uniform load of 13.4 lb per sq ft over the south face of the building (see following Equations (4)).

It may be of historical interest that in order to deny the truth of current reported deflections a communication, signed "Empire State Incorporated," appeared in the *New York Sun* of July 10, 1931. The communication reads:

> "Please be informed that while no gale strong enough to permit measurements to be made has ever been furnished by the elements in New York City, it is a firm belief of the architects and the engineers who built Empire State that the possible swaying of the building in a 220 mile wind would be absolutely negligible. The highest measurement made so far indicates a sway of less than one-tenth of an inch."

Paul Starrett, of Starrett Brothers and Eken, the firm that built the Empire State Building, writes in 1938[27]: "The sway of the Empire State Building has been measured in strong wind-storms and the greatest variation of the mooring mast from the perpendicular was found to be two and a half inches on either side."

The highest velocity recorded in the tables of Professor Rathbun's paper is 90 miles per hr although a velocity of 102 miles per hr is mentioned in the text (see heading, "Velocity of the Wind").

The New York City Building Code for structures higher than 100 ft calls for an assumed wind pressure of 20 lb per sq ft of exposed surface from the top down to the 100-ft level. By an Amendment that became effective March 24, 1930, the requirement in the then existing Code was changed from 30 lb to the present 20 lb. The Empire State Building was formally opened to the public on May 1, 1931. The late H. G. Balcom, M. Am. Soc. C. E., reported[28] that:

[26] *The Structural Engineer,* Vol. XV, May, 1937, p. 186.

[27] "Changing the Skyline: An Autobiography," by Paul Starrett, 1938.

[28] "Wind Calculations," by H. G. Balcom, *Civil Engineering,* Vol. 1, May, 1931, p. 700.

"In wind calculation, the floor construction was assumed to act as a rigid horizontal plate, which distributed the wind pressure to the various bents in the ratio of their resistance. Overturning wind stresses were figured by the cantilever method. The resistance was based on the relative moments of inertia of the different bents; that is, the overturning unit pressure, positive or negative, taken by each column was proportioned to its distance from the center of gravity of the bents."

The paper by Professor Rathbun is an apt rejoinder to a hope expressed by Mr. Balcom in the last sentence of his article,[28] " * * * it is, therefore, greatly to be hoped that the building may be noted, not only for its height and majestic beauty, but also as a means of promoting engineering knowledge."

F. P. Shearwood,[29] M. Am. Soc. C. E. (by letter).—A fascinating problem is treated in this paper in that it deals with one of the major factors in the intricate problem of designing the frame of a high building, safely and economically. The records indicate that the wind forces acting on a high building are not nearly as severe as most building codes specify, and that the effect of gusts does not extend to a great depth. The paper indicates that the resulting forces on the sides of the building are very erratic and may create torsion in the structure.

A most useful and interesting part of the paper is the reference to the great initial resistance of the masonry. Some of this resistance was found to be plastic; that is, the deflection did not recover. This would indicate that movement had occurred between some parts of the material, or, that some permanent stretch or compression had taken place. Masonry has practically no ductility and, therefore, no resistance that is not elastic, except the friction between its particles. The steel frame is wholly elastic for loads far greater than those applied during the tests, with the exception of the possibility that the riveted joints can slip in their holes; but this is improbable at the small wind loads recorded during the tests.

If, therefore, the masonry has practically no ductility and the steel frame connections have not slipped, the plastic deflection of the building must be due to the fracturing of some of the elastic resistance of the masonry, and then to its overcoming the frictional resistance to its slipping on itself or on the steelwork.

A tremendous amount of labor, discussion, and thought has been expended on devising theories for calculating the exact distribution of the resistance to the wind forces on these steel frames, but each investigator disregards a great many actual facts which must modify the theories to such an extent that they probably do not agree, even approximately, with actual results.

To devise an exact solution of theory for such an indeterminate stress problem, and one which is based on very doubtful assumptions, seems like aiming at needless refinement. The resisting frame has many paths of resistance; it is composed of a material that has considerable ductility and elasticity of about twice the amount that is ordinarily utilized in design. Structural designing is restricted and influenced far too much by arbitrary application of unit stresses and other limitations, which are applied impartially to the computed stresses in members. Some of these members must resist the stress without assistance from adjacent members, whereas others, when overstrained, will automatically bring other paths into increasing assistance.

---

[29] Cons. Engr., Dominion Bridge Co., Ltd., Montreal, Que., Canada.

Roughly stated, in designing the frame of a high building the present custom is to consider it on the following bases:

(1) As composed of an articulated frame for calculating the vertical loads;

(2) As composed of independent portal bents with rigid joints for calculating the horizontal forces;

(3) That the wind force is a uniformly applied load; and,

(4) That the steelwork is assembled and fabricated without having initial strain or slackness, and that it is wholly and perfectly elastic.

In actual practice not one of these conditions is quite correct; but it is assumed arbitrarily that they are all correct, and on that basis the stresses are calculated and the material is strictly porportioned.

The important questions raised by the tests in this paper and which require further investigation are: (*a*) Whether the great proportion of resistance that the masonry exerts against the wind forces will be maintained when much higher winds occur; and (*b*) whether, or how much of, this resistance will be fractured and, therefore, destroyed before the wind forces reach their maximum intensities. There might be much insurance against partial damage to the masonry, etc., should severe winds occur, by utilizing more fully the potential stiffening effect of the masonry, anchoring it firmly to the steelwork, and even reinforcing the walls.

These tests show how very problematical are the assumed forces and resistances which are commonly used as the bases of the theories and calculations for designing steel building frames. They indicate that a building should be treated more as a monolithic whole rather than just as an independent frame composed of supports and bents. It is especially important to guard against details that have planes of weakness or relatively excessive or sudden changes in stiffness, where strains will be dangerously concentrated when meeting the general deflections. Finally, they suggest that the stresses given by the conventional theories (which endeavor to distribute, exactly, the indeterminate stresses induced by indeterminate forces) should be used only as a guide, and that engineering judgment and experience should be given greater latitude.

LYDIK S. JACOBSEN,[30] ESQ. (by letter).—A series of interesting tests is reported in this paper, which contains information of great value to the student of structural engineering. From the point of view of fundamental knowledge of the dynamic behavior of a building, the author's observations of the longer of the fundamental transverse periods of the Empire State Building is especially illuminating and is in good agreement with numerous observations made on buildings in California.

Equation (1), in Part II, appears to be somewhat misleading since it applies only to ratios. In other words, T is not the period of vibration; it is only the ratio of what Professor Rathbun calls homologous times. Similarly, W is not the weight of the building or of the model; it is only the ratio of homologous weights or masses, etc. Aside from this obvious over-sight, it is extremely interesting to note that the model period converted to the prototype dimensions becomes 17.8 sec whereas the observed building period is 8.25 sec. Since the influence of the foundation on the fundamental period of the actual building is not well known quantitatively, it was probably not considered in the model, so that the 17.8-sec period obtained by the model must have been based on the assumption of an infinitely rigid foundation. With this in mind, it is obvious that the stiffening effect of the masonry must be somewhat greater than the author's estimate of 350 per cent. Data obtained by the United States Coast and Geodetic Survey[31] on buildings at different stages of construction, support the view that the masonry walls may stiffen the structure as much as ten times the steel frame stiffness.

---

[30] Prof., Mech. Eng., Stanford Univ., Stanford University, Calif.

It is also of great interest to note that between 1932 and 1934 the observed period of the building decreased from 8.38 sec to 8.14 sec. One wonders if the present period of 8.25 sec indicates an actual lengthening since 1934, or if the methods of measuring the periods are really of three-place accuracy. The author's explanation that the shortening of the period is probably due to an adjustment of the several parts of the structure during severe storms is quite plausible, especially if the least known part of the structure—the ground on which it stands—is included. It is suggested that a time record of accurate determinations of periods be continued.

The fact that the building does not have a unique position of static equilibrium, as indicated by the collimator observations, is significant. Undoubtedly, it must be given the author's interpretation as being due to plastic action, within the structure itself, although even in that case the ground effect, if it is nonuniform over the foundations, may account for part of the wandering of the middle position of swing in still weather.

Considering the well-known fact that wind structure, especially during storms, is a very complicated phenomenon,[32] it is not strange that the simultaneous readings of wind velocities obtained at the four stations in the vicinity of the Empire State Building differ greatly. One wonders if the four lengthy pages of Table 1 really justify "considerable detailed study."

Conclusion (1) relating to the complicated and irregular distribution of wind pressure on a building is amply warranted by even a cursory glance at Table 2. It is further corroborated by common-sense observations as well as by the aforementioned technical studies.[32]

The author's derivation of formulas, beginning with Equation (5) and ending with Equation (20), is extremely involved considering that the result (Equation (20)) can be written down almost *a priori* and that Equation (19) simply shows, in integral form, the sum of some of the potential energies divided by the kinetic. Since the author agrees with other investigators about the great stiffening effect of the masonry walls, one is surprised to find that the theory involves only the usual "static" framework consisting of columns and girders, and that the more important members—the walls—are entirely neglected. The writer suggests that, if an explicit formula for the fundamental transverse period is to be developed, a method involving an equivalent cross-section of a homogeneous, although far from uniform, beam may lead to simpler and more accurate results. However, the step-by-step method of calculating the period is patently indicated for a building of as complicated an outline as the Empire State Building.

[31] Preliminary Repts. of U. S. Coast and Geodetic Survey's California Seismological Program.

[32] "Wind Structure in Winter Storms," by R. H. Sherlock, M. Am. Soc. C. E., and M. B. Stout, *Journal of the Aeronautical Sciences*, December, 1937.

In spite of this seemingly critical discussion of the paper, the writer wishes to record his great appreciation of this interesting and important contribution to the knowledge of the dynamic behavior of buildings.

Francis L. Castleman, Jr.,[33] **Assoc. M. Am. Soc. C. E.** (by letter).—The Technical Research Committee of the American Institute of Steel Construction, and the owners, architects, consulting engineers, and contractors for the Empire State Building are to be congratulated on the foresight shown in equipping this building in such a manner that pertinent data on wind and its effect could be recorded. Professor Rathbun has presented an interesting and worthy paper describing these data and it should stimulate interest in their proper evaluation. Quantitatively, many more large-scale experiments appear necessary before any definite interpretations or conclusions can be drawn; but, qualitatively, the data submitted tend to clarify and sustain some common conceptions on this intricate subject.

Constructive criticism would point to the relative brevity of the paper. As the work extended over a period of five years, considerably more explanatory data might have been inserted at the expense of brevity. On first reading, the paper appears somewhat voluminous, but on detail study the writer thought certain parts meager and fragmentary.

Although this building is monumental in that it is the tallest ever built, there is a particular property it has in common with many other buildings; namely, the ratio of its maximum height to its least width is less than 8. A maximum height of 1 049 ft and a least width of 134 ft are assumed. This feature is emphasized in the hope of encouraging like studies on buildings with a similar ratio, but of not such great height. The writer knows of several buildings exceeding this ratio.

A theoretically correct mathematical analysis, taking all factors and their combined effect into consideration, would be difficult for a structure of this nature. The bracing in the central bays around the elevator shafts, plus the shallow "knuckle" wind-bracing, constitute a combined system which, when considered as a unit, forms a complicated but effective arrangement. This should be borne in mind when interpreting much of the data submitted.

As stated in the paper, the plastic action of the surrounding material has a marked effect in reducing deflection and vibration at ordinary wind loads—even at high wind loads. In the present state of knowledge, however, it is doubtful whether these materials should be counted at extreme loadings, as their beneficial effects under such conditions are reduced. Extreme loadings occur perhaps only two or three times in the life of such a structure; but on such occasions it must be able to sustain them adequately. Mr. Charles B.

---

[33] Associate Prof., Structural Eng., Vanderbilt Univ., Nashville, Tenn.

Driscoll[34] has commented interestingly on his esoteric experiences during a recent storm as follows: "Yes, the tall towers swayed. Some of them rather sickeningly. There were plenty of towers in which office employees became seasick during that stormy afternoon. * * * A good many were excused from work." These remarks from a layman should be convincing in themselves.

Although the Empire State Building is much higher than its neighbors, the latter will have a considerable effect on the resulting action of the wind. Until wind-tunnel methods are modified to make allowance for this effect, as well as other factors, experimental data based on such methods can be of little help.

The wind records given in Table 1 are particularly enlightening and, as the author states, justify considerable detailed study. Twenty-three items in this table show wind velocities of 50 miles per hr, or more. Using the well-known relation, $p = 0.003\ V^2$ for a 50-mile wind, $p = 7.5$ lb per sq ft; for a 70-mile wind, $p = 14.7$ lb per sq ft; and, for a 102-mile wind, $p = 31.2$ lb per sq ft. It is assumed in the foregoing that true and not indicated velocities are dealt with. (Lack of this distinction is a source of continual annoyance and error in many published data.) In the storm that swept over a part of New England in September, 1938, an Associated Press Dispatch of September 23 stated that wind gusts of approximately 173 and 186 miles per hr were recorded at the Harvard Meteorological Observatory. In design, usually, the average speed over a few minutes is considered satisfactory, but there is a school of thought which maintains that extreme velocities should be used. From the data supplied, and considering its erratic nature, it would seem that 20 lb per sq ft taken by the frame alone is not over-conservative in the vicinity of New York City. Table 1 indicates that the pressure varies with the height (which has long been known), but that there appears to be no discoverable law of variation for such a densely built area. Many building codes allow for this condition by varying the pressure approximately directly as the height, with certain fixed limitations. Considering the present state of knowledge this may be a wasted effort complicating the work of the structural engineer. Until more data are forthcoming, the best that can be done is to use a sum total effect that approximates the actual conditions in the light of present-day knowledge, in an endeavor to produce an adequate structure from the standpoint of human safety and comfort, rather than from that of cost. This is not as easy as it sounds.

From a meteorological viewpoint three weather bureaus on Manhattan Island may be sufficient, but from the standpoint of the structural engineer, or rather the data that should be furnished to him by the meteorologist, this number would appear deficient.

Fig. 8 seems to indicate that on the windward side of the building the air currents tend down, whereas on the leeward side the tendency is upward. As Fig. 8 is indicative of a single observation it would be interesting to know if this is true in general, or even approximately so. The manometer readings exhibit qualitatively the complex action of the wind and the great variations in pressure both positive and negative. However, as Professor Rathbun states, they are not to be taken as giving a true picture of the actual forces acting on the building. Although the influence of temperature on deflection has been shown to be negligible on this building, the writer would be wary as to accepting this in principle. With the rapid developments made in light-weight covering, and considering similar future advances, this might not always be true, by any means.

---

[34] "New York Day by Day," McNaught Syndicate Inc., *Nashville Banner*, October 5. 1938, p. 9.

The author has made computations assuming the structure to be a cantilever, applying the well-known flexure formula, $s = \frac{M\,c}{I}$. As he states, this presupposes that the twenty-fourth and twenty-fifth floors remain planes after elastic action from wind has occurred. With the use of the "knuckle" wind connection, this is questionable. Although this type of connection has strength, it is relatively deficient in stiffness. Such computations should be accepted with reservations. Columns (13) and (14), Table 6, would seem to support this view. Furthermore, as one of the studies contemplated was, "a check, or refutation, of the basic principles of the portal and cantilever methods of analysis," the writer cannot help but wonder why the portal method was not at least touched upon for comparative data. However, it is only fair to state that for this building, with a double type of wind-bracing, any method, theoretical or otherwise, will be difficult to apply as the division of wind loading between the two systems leads to complicating ramifications.

It is stated that the plasticity of the surrounding materials has a dampening effect on the vibrations, but does not alter the period. This is true but does not tell the entire story as to ultimate possibilities which might occur. Although the possibility is remote, the disturbing wind forces might sometimes approximate a periodic nature for a short interval setting up a tendency toward a forced vibration. If the frequency of the disturbing forces is seriously different from the natural frequency the resulting vibrations will be small. If by chance the two frequencies are equal, or only approximately so, the amplitude is increased enormously.

In computing the equivalent uniform load by means of the model and graphical integration a minimum reading of 3.26 in., as given in Table 3, under Item No. 115, might be a more conservative value to use in the absence of detailed explanation. The deflection would then be $\Delta = 3.25$ in. The ratio of this deflection to that produced by a 1-lb load on the model would be $\frac{3.25}{0.0488} = 66.6$. The new horizontal pull at the eighty-sixth floor necessary to produce this deflection would be $P = \frac{66.6 \times 50\,530\,000}{(60.484)^2} = 919\,900$ lb. From the curves of Fig. 18 the same deflection would be produced by a uniform load over the north face of $\frac{919\,900}{64\,600} = 14.24$ lb per sq ft (including negative as well as positive pressure). As Professor Rathbun states, such a value should be considered with caution.

It would appear that Equation (18) lacks one term. The direct stress, s_1, in a beam at any floor level will be proportional to the difference of the shear below and above the level considered. Therefore:

$$s_1 = \frac{p_1}{q_1}\left(\frac{4\,\pi^2}{T^2}\right)\int_{x_1}^{h} m\,y\,dx \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

in which p_1 and q_1 are abstract dimensionless numbers. The energy in a beam under axial load is, $W_b = \dfrac{s_1^2\,L}{2\,A\,E}$, or,

$$W_b = \frac{L}{2\,A\,E}\,\frac{16\,\pi^4}{T^4}\,\frac{p_1^2}{q_1^2}\left[\int_{x_1}^{h} m\,y\,dx\right]^2 \ldots\ldots\ldots\ldots (22a)$$

and for all beams it will be,

$$\sum W_b = \frac{16\,\pi^4}{2\,T^4}\sum\frac{p_1^2}{q_1^2}\,\frac{L}{A\,E}\left[\int_{x_1}^{h} m\,y\,dx\right]^2 \ldots\ldots\ldots\ldots (22b)$$

Using capital letters for the dimensionless terms this will reduce (after multiplying through by T^4) to,

$$T^4\sum W_b = G\sum\left(\frac{L}{A\,E}\right)\left[\int_{x_1}^{h} m\,y\,dx\right]^2 \ldots\ldots\ldots\ldots (23)$$

The term on the right-hand side of Equation (23) should appear in the right-hand side of Equation (18). If it is admissible to neglect the third term in Equation (18), the term developed in Equation (23) can probably be neglected. For tower buildings the axial distortions of the columns are considerable and it is a question as to whether the third term in Equation (18) should be neglected. If it were necessary to consider it, much of the work of the author's paper might be invalidated as the area of the columns and beams of the model does not bear the proper similitude to the building itself. More information concerning the building and model would appear necessary to evaluate properly the weight that this term carries.

J. B. WILBUR,[35] ASSOC. M. AM. SOC. C. E. (by letter).—The subject of stresses in building frames due to lateral forces is as complicated as it is important. It is a problem that may be broken down into a large number of subdivisions, each one of which is so complicated as to discourage the hope of satisfactory solution without extended studies and research. It is only by the constant investigation of the various problems involved that satisfactory methods for the design of the frames of tall buildings may eventually be discovered. Professor Rathbun's data and discussions are especially helpful inasmuch as they are based on the action of an actual building.

The stiffening effect of the masonry of a building, as Professor Rathbun states, is a problem of considerable importance. Although it is undoubtedly important under most conditions, it is probably true that the stiffening effect of the masonry becomes of less importance as the loads increase. In the First Progress Report of the Committee on Steel of the Structural Division (Sub-Committee No. 31 on Wind Bracing in Steel Buildings),[36] the suggestion was made that judgment as to the stiffness of a building be based on a deflection index. This index was defined as the maximum deflection at the top of a frame (under maximum wind load and assuming the frame to carry the entire wind load) divided by the height of the frame. It was recognized that under normal conditions the deflection index corresponds to some multiple of the deflections that will actually occur, but the deflection index was suggested, nevertheless, as a convenient standard by which to judge the probable stiffness of a building. Although the use of the deflection index is open to criticism because of the fact that so much is left to judgment, in respect to the stiffening effect of masonry, the writer knows of no better practical approach to the problem. Some of Professor Rathbun's data should be of real value in applying the judgment factor in the use of the deflection index.

---

[35] Associate Prof. of Civ. Eng., Mass. Inst. Tech., Cambridge, Mass.

[36] *Civil Engineering*, March, 1931, p. 478.

When one wishes to make use of the deflection index, the question arises as to how to compute the deflection of the top of a building frame under the action of lateral loads. If a complete analysis of the frame has been made, this is easily accomplished by considering the action of one column stack by itself, and applying the moment-area method. It is often desirable, however, to estimate the deflection index without a complete stress analysis for the frame. Investigations by the writer have shown that deflection computations based on moments as analyzed by easily applied methods, such as the portal and cantilever methods, are likely to be seriously in error. In the belief that an approximate slope deflection solution might be used to advantage in this problem, an investigation was conducted, in 1933, under the supervision of the writer, by William Niessen, Jun. Am. Soc. C. E., and Mr. R. J. Stoddard.[37] The procedures followed were similar to those suggested by the writer in a previous publication dealing with an approximate slope deflection determination of moments in building frames due to lateral forces.[38] The method of distributing wind loads to the bents of a building which resulted from this investigation has been presented elsewhere,[39] but an interesting result of this research, which was not cited at that time, consisted of a method for determining the deflection of the top of a building bent, which is not only easily applied, but which is reasonably accurate. In the Appendix of that paper,[39] it was shown that, approximately,

$$\delta_o = \frac{H_o\,h_o}{24\,E}\left(\frac{2}{\sum K_{co}} + \frac{1}{\sum K_{ga}} + \frac{1}{\sum K_{gb}}\right)\ldots\ldots\ldots\ldots(24)$$

In Equation (24), all symbols apply to one bent only, as follows: δ_o = the increment to horizontal deflection occurring in a given story which is denoted by the subscript, o; H_o = total horizontal shear on the given story; h_o = height of the given story; E = modulus of elasticity of the material of the bent; $K = \frac{E\,I}{L}$ for a member, in which I and L are moment of inertia and length, respectively, for the member; $\sum K_{co}$ = the sum of the K-values for all the columns of the given story; $\sum K_{ga}$ = the sum of the K-values for all the girders of the floor directly above the story under consideration; and, $\sum K_{gb}$ = the sum of the K-values for all the girders of the floor directly below the story under consideration.

---

[37] "A Theoretical Investigation to Determine the Proportion of Wind Pressure Carried by the Various Bents of High Buildings," by W. Niessen and R. J. Stoddard. Submitted, in May, 1933, in partial fulfillment of the requirement for the degree of Master of Science.

[38] "A New Method for Analyzing Stresses due to Lateral Forces in Building Frames," by John B. Wilbur, Assoc. M. Am. Soc. C. E., *Journal*, Boston Soc. of Civ. Engrs., January, 1934.

[39] "Distribution of Wind Loads to the Bents of a Building," by John B. Wilbur, *loc. cit.*, October, 1935.

To obtain the deflection of the top of a bent, Equation (24) is summed up for all the stories of the bent:

$$\delta_{\text{top}} = \frac{1}{24\,E} \sum_{\text{basement}}^{\text{roof}} \left[H_o\, h_o^2 \left(\frac{2}{\sum K_{co}} + \frac{1}{\sum K_{ga}} + \frac{1}{\sum K_{gb}} \right) \right] \ldots\ldots (25)$$

In Equation (25), $\frac{1}{\sum K_{gb}}$ equals zero for the basement if the columns are considered as fixed at their base, since this condition is equivalent to girders of infinite stiffness.

Equation (25) may be evaluated directly for any given bent, if the loads acting on the bent and the make-up of the members are known. Comparing the deflections of the tops of nine different bents of varying arrangements and sizes as computed by Equation (25), with corresponding deflections based on so-called exact solutions by the slope deflection method, it was found that the average error resulting from the approximate nature of Equation (25) was 5%, whereas the maximum error was 13.5 per cent. In view of the fact that deflection indices based on these deflections would be used only as a guide to judgment in estimating probable building stiffness, the accuracy obtained is undoubtedly sufficient for practical purposes.

R. D. SPELLMAN,[40] ASSOC. M. AM. SOC. C. E. (by letter).—Regarding the effect of masonry upon the rigidity and strength of a building against wind pressure, as treated in the paper by Professor Rathbun, the writer would like to call attention to some observations made in Miami, Fla., after the 1926 hurricane. All the larger buildings in Miami, and especially those few which were structurally damaged by the hurricane, were inspected by the writer with the aid of the plans and specifications.

In most of the buildings damaged some kind of wind-bracing was included in the structural steel frame. Several were quite thoroughly designed, and, in others, the wind-bracing was covered by calling for top and bottom angles in the specifications. However, there was no apparent relation between the amount of the wind-bracing provided and the damage done to the different buildings. Some of the better designed buildings were damaged to a greater extent than others with practically no wind-bracing in the structural steel frame. The writer suspected that this inconsistency was due to the stiffening effect of the masonry. Calculations were made for each building to determine the unit shear on all masonry walls caused by the total wind load on the building above the floor where the greatest damage occurred. It was discovered that the damage was in close ratio to these unit shears.

---

[40] Chf. Engr., Rust Eng. Co., Pittsburgh, Pa.

When the calculations were made, a value of 60 lb per sq ft was assumed as the maximum pressure reached during the hurricane. The unit shears varied from about 40 lb per sq in. to 110 lb per sq in. in the Meyer Kiser Building, which failed completely near the sixth floor. Another building which had a unit shear of 75 lb per sq in. was damaged quite badly. As the shears were reduced to nearly 50 lb, the damage was quite small, and one building with practically no wind-bracing, but with a unit shear of about 40 lb, had only a few cracks in the plaster on the first floor. This building, however, was better protected by other buildings than most of those damaged severely. All the foregoing calculations were made hurriedly and no specific value should be attached to them, except to note that the damage was in proportion to the unit shears on the masonry walls of the buildings, and perhaps to show about where damage may be expected to begin. All the aforementioned buildings were between fifteen and thirty stories high.

Most buildings in Miami, and especially those referred to herein, are constructed with light masonry walls; buildings of the same class in New York City, or other parts of the United States, would have 50% to 100% more cross-sectional area of masonry walls.

It is not the writer's intent to leave the impression that damage was caused to some of these buildings in spite of the fact that they were provided with adequate wind-bracing in the structural frame. Had they been properly designed, it is certain that no damage would have occurred; for example, the Congress Building had been carefully designed for a wind pressure of 25 lb per sq in. and, at the time of the hurricane, had reached that stage in the construction at which all the exterior walls were completed but few of the interior walls and partitions had been installed, giving it the maximum wind load with the minimum masonry resistance.

Commenting on Conclusion (8) of the paper, it would seem that in some instances, depending on the proportions of the building and the quantity and distribution of masonry therein, a substantial saving could be attained safely by omitting the wind-bracing in the structural frame. This might apply to the entire building, or to the upper parts of most buildings. Perhaps the point at which this wind-bracing might be omitted could be determined at a certain unit shear on the masonry walls. When the unit shear exceeded this value, the entire load would then be taken by the structural steel frame, and the masonry disregarded both for strength and stiffness.

DAVID A. MOLITOR,[41] M. AM. SOC. C. E. (by letter).—The most complete answer hitherto published, relative to the actual functioning of the steel frame of a tall building, is contained in this paper. The author's findings, based on the observations and measurements made during high winds, at various times, over a period of years, constitute a valuable contribution to knowledge.

The assumptions which have served as criteria in formulating methods for the design of tall buildings, crude as they are, have generally given very satisfactory results in producing tenantable structures. However, these achievements have been attained by a process of gradual evolution, in which the progressive steps from smaller to taller buildings were verified by actual structures, each time after venturing a little higher than in previous cases; and now the profession learns from a large full-sized model (the Empire State Building) that the assumed design unit stresses for resisting wind loads are about three times those actually occurring in the steel frame when subjected to such wind loads; and, that the maximum deflection at the top of the cantilever is only about one-third as much as would be expected if the steel frame were fully loaded and stressed according to the design assumptions.

---

[41] Cons. Engr., Harlingen, Tex. Mr. Molitor died September 8, 1939.

Some years ago the writer attempted to appraise the relative stiffness of a building frame as affected by the contributing stiffness of the architectural clothing,[7] and, strangely enough, arrived at a conclusion which is now found to check remarkably well with the results of the actual measurements obtained on the Empire State Building. These findings prompted the writer to express the opinion that all refinements pertaining to wind stress analyses in building frames border on wasted energy, and that rational design methods only could lead to satisfactory and economic construction.

The deflection of a 40-story building frame was computed to be 6.5 in., on the assumption that the frame carried the entire wind load of 15 lb per sq ft on the basis of 24 000-lb unit stress. The probable deflection of this building would not exceed 1.5 in., leading to the conclusion that buildings thus designed would deflect three to four times as much as they actually do. In other words, the architectural clothing, and not the steel frame alone, is responsible for the rigidity found by experience to be manifested in present-day tall buildings.

Were it not for the inherent rigidity of the architectural clothing of the steel frame, current design assumptions would be seriously deficient. Fortunately, the combination of a flexible steel frame, designed for certain wind loads and unit stresses, with a comparatively rigid fill material such as concrete, does produce tall buildings with tenantable rigidity. There is one mitigating circumstance which makes vibratory disturbances more tolerable, and that is the period of the vibration which may vary from 5 to 10 sec.

However, rigidity constitutes an important asset to the owner of a building, and the degree which the steel frame alone contributes to this factor, despite the severe load assumptions, is, in fact, relatively insufficient to supply the necessity.

In view of the foregoing and the substantial agreement with the findings presented in the paper, it would be very risky to adopt any changes in the present methods of design, or to choose different kinds of steel such as silicon steel, with higher unit stresses which would result in more flexible frames, thus incurring the danger of introducing new difficulties which might easily result in untenantable buildings. If such an error of judgment were committed in a design, the result might produce failure of the financial undertaking.

It would be highly desirable to have similar measurements made on other new buildings so as to add more of the valuable data to present knowledge on this subject. However, the irrefutable facts presented in this paper should put a quietus on most of the theoretic speculations indulged in by writers on this subject, and designers should continue to use the simple approximate methods which have given such good results in practice.

Walter J. Gray,[42] **Jun. Am. Soc. C. E.** (by letter).—Adding to the interesting record of the variations of wind action on the Empire State Building, as reported by Professor Rathbun, is the observed fog characteristic shown in Fig. 23. As indicated, the fog formed a "wake" on the north face of the building, contracting to a neck at a distance of about 100 ft from the structure and then suddenly spreading again to dissipate itself in the direction of the wind. The phenomenon was visible from the street level since the concentration of fog in the "wake" caused it to appear darker than the surrounding fog body.

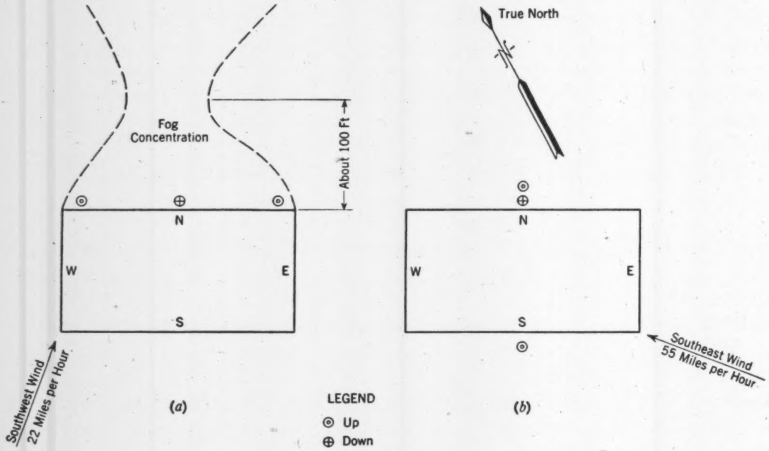

Fig. 23

This "wake," similar in character to the phenomena explained in texts on aerodynamics, substantiates the existence of a negative pressure on the far side of the structure, which characteristic is indicated by the manometer tube readings in Fig. 10 of the original paper. At the time of the observation, air currents close to the building indicated only vertical movements on the north face. The observation was made at a time of low wind velocity as shown by the anemometer at the top of the building. Subsequent observations in a heavy fog failed to indicate that the visible phenomenon occurred at higher wind velocities. The observations shown in Fig. 23(*b*) were taken under fog conditions similar to those of Fig. 23(*a*), but no "wake" was seen in the case of the higher velocity. It would appear that although a negative pressure exists at higher velocities, its visible evidence is destroyed by the gusty character of the wind.

K. L. DeBlois,[43] **Assoc. M. Am. Soc. C. E.** (by letter).—The vibration tests on the model as described under the heading, "Description of the Models," provide an opportunity to measure the damping. The shape of the curves shown in Fig. 20 indicates that damping is due to elastic or internal friction of the material, and, being proportional to velocity, the damping has the effect of reducing the oscillations in geometrical progression.[44]

---

[42] Eng. Asst., Dept. of Public Works, New York, N. Y.

[43] Engr.-Structural, U. S. Engr. Corps, Pittsburgh, Pa.

The equation of the curve connecting the extremities of the oscillations in Fig. 20 is given by,

$$\alpha_r = \alpha_0 \, e^{-2\pi\delta t} \qquad \text{(26)}$$

in which α_0 is the initial amplitude; α_r is any succeeding amplitude; t = elapsed time; and, δ = damping coefficient.

From inspection of Equation (26) it is evident that any convenient scale may be used to measure α_0 and α_r. Using Fig. 20(*b*): $\alpha_0 = 0.27$ in.; $\alpha_r = 0.01$ in. after 31 vibrations; $t = 4.0$ sec; and, T = period $= \frac{4}{31} = 0.129$. Substituting these values in Equation (26): $0.01 = 0.27\, e^{-2\pi\delta 4.0} = 0.27\, e^{-25.13\delta}$; from which, by logarithms, $\delta = 0.131$, and the damping factor, $e^{-2\pi\delta T} = 0.90$. This damping factor expresses the rate at which the vibrations tend to disappear; that is, the amplitude of any vibration is 0.90 of the amplitude of the preceding one on the same side of the axis.

Applying the same procedure to the building, which has an observed period of 8.25 sec, and assuming that the ratio of the amplitudes after 31 vibrations is the same as in the model: $t = 8.25\ (31) = 255.5$ sec; and, $\delta = 0.002$.

ALBERT SMITH,[45] M. AM. SOC. C. E. (by letter).—A large mass of original data is presented in this paper, which should be analyzed carefully to reveal all the information it will yield. From Table 1, the writer took all the items in which the velocity was as great as 30 miles per hr at the Empire State Building, and separated them into 16 compass directions. For each direction the average of the velocities was computed for the Empire State, the Daily News, and the Whitehall Buildings. (It is assumed that all readings have been corrected, and can be compared.) The numbers of readings are plotted in Fig. 24. The approximate effective depths of wind current are as follows:

Buildings	Depth, in feet
Empire State (1 263 − 100)	1 163, or less
Daily News (504 − 100)	404, or less
Whitehall (within a horizontal arc of 247°)	454

The dotted line for the Daily News Building and the full line for the Whitehall Building show ratios of the average velocity in each direction, to the average velocity at the Empire State Building in the same direction. Within an arc of 112° the high buildings near the Whitehall Building evidently reduce the velocity; and at the Daily News Building the influence of the Chrysler Building on the velocity of west northwest winds is clearly visible. Over an arc of 247° the Whitehall Building has a larger wind current depth than the News Building, and averages 0.617% as compared with 0.51% for the News Building. One would not expect so great an increase in velocity between 500 ft and 1 200 ft of height. These data seem to indicate that the idea of using a uniformly increasing pressure, advanced by H. V. Spurr, M. Am. Soc. C. E.,[10] is better than making no increase above 500 ft. Actually the readings indicate about four times as much pressure at the top of the Empire State Building as at the top of the News Building. It is likely, however, that the "20-yr wind," of much greater velocity than any measured in these tests, will have a velocity more nearly uniform above the 500-ft level. Returning to the consideration of shelter, winds from the south southwest appear to have a clear sweep for a long distance before reaching either the News or the Empire State Buildings, and one might expect the News velocity ratio be be high for this direction, instead of which it is about average. On the whole, there seems to be no evidence that anything except the very high Chrysler Building affects velocities at the News Building, and that therefore the velocities at the Empire State Building have not been reduced by the influence of other buildings.

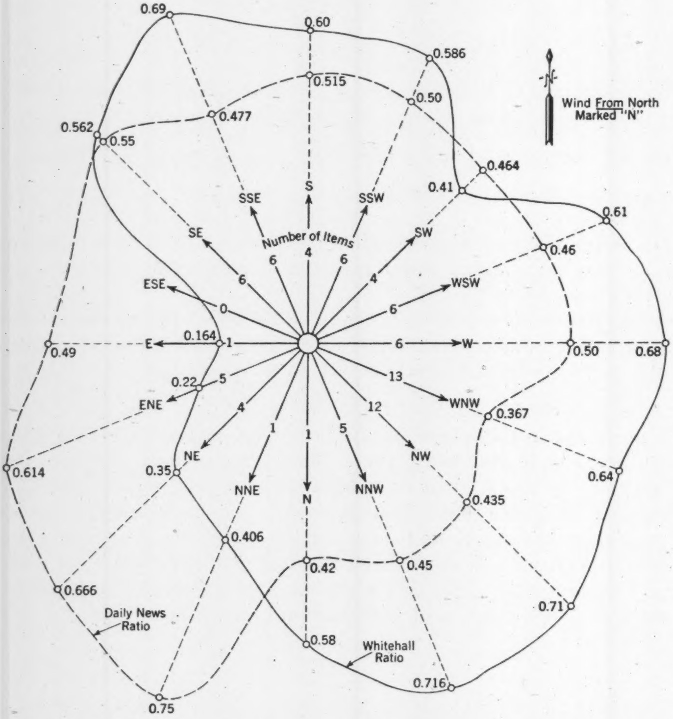

FIG. 24.—WIND VELOCITIES OF 30 MILES PER HOUR, OR MORE, AT EMPIRE STATE BUILDING

Manometer Readings.—The writer can see no possibility of error in the preparations for these tests. In a multi-story building there may be a difference in the interior air pressure at different stories; but the difference is small, and would not affect the total force. Since the pipes leading from the wall openings were very different in length, Tubes No. 3 and No. 8 (Fig. 4) would be much more responsive to gusts than the others; but this should not cause large errors. There are a large number of cases in which the approximately simultaneous readings at the stations on the same floor are of magnitude and sign that contradict all previous data from manometer readings. It may be that the 90-mile wind illustrated in Fig. 10 changed 90° between the readings of the two sets of five tubes each, and that this accounts for positive readings at both Tubes No. 7 and No. 4, but the writer cannot account, in Fig. 10(*c*) for readings in a 90-mile wind of simultaneous pressures at Tubes No. 6 and No. 10. He suggests that the sign for Tube No. 10 has been recorded in error. The same comment applies to the reading on Tube No. 10 at 50 to 60 miles per hr (Fig. 10(*c*)).

Of thirty-seven complete sets of observations for the seventy-fifth floor, eleven contain readings which contradict each other, and all sets exhibit slopes in the pressure diagram which differ very greatly from all those previously recorded. The air tunnel results of Messrs. Dryden and Hill[3] are consistent and explainable. Although the structure of the air that blew against the seventy-fifth floor was more variable than that in the wind tunnel at the National Bureau of Standards, it was probably less complicated than that in which the writer's observations were taken on the campus of Purdue University, Lafayette, Ind.[46] When plotted, his results were consistent internally, except for such variations as should be expected in light winds and near the ground, and agreed very well with wind-tunnel tests. For this reason he would like to know much more about the technique of the author's readings before he revises his ideas of how the wind forces are distributed.

Extensometer Readings.—Some of these readings correspond to a stress computed for the observed velocity, but many do not. Observations No. 9 and No. 10, Table 6, with the same velocity and direction of wind, show stresses of +223 and −343, respectively. Observation No. 26, during a south southwest wind of 30 miles per hr, showed a column stress of −488 lb per sq in., which would check quite well if it had been +488. Observation No. 28, during a south southwest wind of 18 miles per hr, showed a column stress of +59 lb per sq in., which, although correct in sign, is low in amount.

There is no mention in the description of the insulating precautions. Undoubtedly, some precautions were taken, but it is possible that they were not adequate. The largest fiber stress derived corresponds to about 4° differential in temperature between the rod and the column, and when the effect of a cold wind on this column above the twenty-fifth floor is considered, and the rapidity with which the twenty-fourth-story column would lose heat, it seems clear that the measuring rods should be insulated very carefully, or that exact temperature corrections should be made.

Plumb-Bob Readings.—The readings in Table 3 show something that one knows must occur, but which heretofore lacked proof. Fig. 12 indicates a "no man's land" under the bob about 1 in. in diameter. The tests prove that the eighty-sixth floor does not return to the same position each time when the wind becomes still, and that it is held away from the unstressed position a distance of the order of 0.5 in. The explanation of this phenomenon lies in the masonry envelop, which is of enormous stiffness against lateral forces, and has little strength. If it carried its own weight it would have great resistance to horizontal shear. Since it is supported at each story, the top layers of masonry in each story slide under horizontal shears, and the frictional resistance to sliding back prevents the building from returning to a zero position and keeps a small stress in the steel frame after the wind subsides. Except for this yielding resistance of the masonry the maximum deflections would be somewhat greater. In some of the top stories the masonry may carry nearly all of the wind shear, whereas in the lower stories it carries only a small part. In the lower stories the resistance of the masonry will not increase much as the wind force and the deflection increase. It is for this reason that structural engineers should neglect the masonry resistance in designing for wind loads. In the vibration of buildings, where the shears are small, the masonry plays an important part in determining the period and amplitude. The structural designer probably cannot do much to affect the vibration. The window area, type of masonry, and the character of the joint under the spandrels are more influential in respect to vibration than the stiffness of the structural frame.

---

[46] "Wind Pressure on Buildings," *Journal*, Western Society of Engineers, December, 1912; also, "Wind Loads on Buildings," *loc. cit.*, April, 1914.

A total deflection normal to the long axis of only 1.75 in. seems very small, but this was under a maximum velocity of only 50 miles per hr. Under 100 miles per hr the force would be four times as large, and many masonry joints, heretofore unstirred, would open and increase the deflection.

VICTOR R. BERGMAN,[47] ASSOC. M. AM. SOC. C. E. (by letter).—In Part II, under "Introduction," Professor Rathbun states that "Rigidity is of considerable importance inasmuch as it affects the popularity of a building with tenants." This aspect of the problem is naturally uncertain and debatable. However, a structure that is too flexible may show a definite economic loss to the owner because of increased maintenance costs directly ascribable to lack of rigidity.

The writer has in mind an office building with a tower extending upwards beyond the 500-ft level above the street. After every heavy wind storm considerable plaster cracking is reported. For example, on Sunday, January 22, 1939, the wind velocity rose to 56 miles per hr; the next day no less than sixty-one complaints concerning cracked plaster deluged the maintenance department of the building! As might be expected, most of the cracks occur in the lower stories of the tower. They appear in the plastered gypsum block partitions, usually horizontally at the ceilings, or vertically at the ends. Apparently the cracking does not occur in the plaster on the brick panel walls, the "skeleton walls" of the building.

That this building sways during a heavy windstorm is patent even to a casually observant tenant of any of the uppermost floors. Some of the electric-light fixtures are suspended from the ceilings by means of tubes which have a universal joint arrangement at the upper ends. At times, their movement is quite perceptible.

---

[47] Estimator and Engr., Godwin Constr. Co., New York, N. Y.

During a heavy gale in 1938, two young women were permitted to leave their work to go home, following their pleas that they were suffering from "seasickness." Strangely enough, the tenants, with the foregoing exception, have not complained about the swaying of the tower. Indeed they seem to expect it and to look for it. The maintenance department of the building has even received telephone calls from the tower tenants concerning the swaying of suspended objects. "Do come up," they sometimes say, "it's very interesting."

Evidently the "scientific" articles on the subject, as "ladled out" by the Sunday supplements, have had a reassuring effect.

OTTO GOTTSCHALK,[48] ESQ. (by letter).—In presenting field-tests data pertaining to the effect of masonry on a structural steel building frame, the author has certainly stirred up a desire to learn similar facts about as many existing tall buildings as possible. The opportunity to compare the behavior of a building with a true model of its skeleton will not occur frequently. This suggests that there should be more simple methods of determining the same information.

In 1938,[49] the writer presented a simple method of computing wind stresses (especially column pressures) from a general model analysis. If the column pressures are known, the distribution of the stress between various columns can be computed by this method. They can be computed, furthermore, from the shortening or lengthening of the columns in a building and, approximately, from the difference in elevation between corresponding points on adjacent columns.[49] It should be easy and inexpensive to weld special bolts or sockets to the field frame at several floors of existing buildings. Since the period of vibration of tall buildings is always equal to several seconds, it will be possible to obtain the change of level between column points originally at the same level by a simple device such as a water-level which can be adjusted to permit accurate readings to within 0.002 in. Such readings will supply extremely valuable information as applied to columns that are either isolated or embedded in walls or partitions, and also would offer a means of appraising the effect of the masonry covering.

COLIN SKINNER,[50] ASSOC. M. AM. SOC. C. E. (by letter).—In designing tall buildings numerous assumptions must be made in order to simplify the work to a practical degree. It is not rational, however, to go to great extremes in refinement of structural design unless the basic assumptions are substantially correct. Too much time and effort have been spent on devising methods of calculating wind stresses in tall buildings, based on the assumption that the steel frame carries all the stress, when it is obvious that the other materials increase both the strength and stiffness of a building. The data in Professor Rathbun's paper may not be complete, but it contains considerable useful information which should serve to stimulate a fresh approach, based on more logical assumptions. The American Institute of Steel Construction and the owners of the building should be congratulated for sponsoring this program and for permitting publication of the results.

[49] "Simplified Wind-Stress Analysis of Tall Buildings," by Otto Gottschalk (see this volume of *Transactions*).

[50] Coordinator, Region 2, USHA, Washington, D. C.

In 1932 the writer made a series of observations on the various instruments installed in the Empire State Building for measuring wind pressure, deflection of the building, and stresses in the steel frame. A considerable number of observations were made over a 2-yr period, and many of these are included in Professor Rathbun's paper. In addition to these data, however, there are several additional observations which may help in interpretation of the published data.

For approximately six months after the building was completed, the strain gages on several columns immediately below the twenty-fifth floor showed no change in stress, regardless of the intensity of the wind. The plastered partitions surrounding the elevator shafts and public halls, the concrete floors, and the exterior masonry walls stiffened the building to such an extent that practically no wind stress was transmitted to the steel frame.

First Big Storm.—Early in March, 1932, a severe storm hit the building with an indicated wind velocity averaging about 70 miles per hr, and gust velocities of more than 95 miles per hr. During this storm a series of muffled explosions were heard and some cracks developed in the masonry materials. At that time (1932) there were no tenants in the building between the twenty-fourth and the eightieth floors, with the exception of a few offices on the forty-first floor. The partitions surrounding the elevator shafts, public halls, and utility rooms (see Fig. 4) were all in place, however, and probably contributed to a large extent to the stiffness of the building.

A visual inspection made the day after this storm showed very few cracks in the partitions surrounding the elevator shafts. Diagonal cracks were observed in several office partitions perpendicular to the exterior wall on the forty-first floor, and in the partitions surrounding a motor room on the twenty-ninth floor. Cracks were also observed in the concrete floors at the first row of interior columns, parallel to the exterior walls.

These floor cracks seemed to indicate that the exterior columns were carrying a substantial portion of the direct stresses, in accordance with the portal theory. It should be noted, however, that the central core of the building contains deep knee-braces and many plastered partitions which undoubtedly restrained the floors from rotating in accordance with the cantilever theory. Furthermore, the floors were about a year old at the time of this storm, and the natural shrinkage of the concrete had probably produced internal tensile stresses which may have been close to the ultimate strength of the concrete. Many additional cracks have occurred in the floors since this storm as mentioned subsequently herein.

Groaning Period; Vibration.—On October 6, 1932, another severe storm occurred (Table 1, Item No. 82) with indicated wind velocities averaging about 70 miles per hr from the south southeast. During this storm the strain gages on the twenty-fourth-story columns moved back and forth very slightly, indicating that the steel frame was beginning to carry a small portion of the wind load. Groans could be heard as the vibration of the building apparently caused slipping between the steel frame and the masonry or grinding in the cracks, which had occurred in the first big storm. With each succeeding storm the groans caused by vibration decreased in intensity and the strain gages apparently became more sensitive, indicating that the building was becoming more flexible and that the steel frame was gradually assuming a larger percentage of the wind load.

After the storm of November 1, 1932 (Table 1, Item No. 102), it was noticed that winds of 30 to 35 miles per hr, against either of the broad faces of the building, would cause the strain gages to oscillate; but winds below this range caused no apparent change of stress in the steel. This indicated that the force of a 30- to 35-mile wind was required to overcome the internal friction and to cause the masonry to slip on the steel or along existing cracks. Thus, a severe storm would deflect the building several inches; then, as the wind subsided, the deflection would decrease until the internal friction was equal to the restoring force of the deflected building. The building would then remain in this partly deflected position until the next severe storm.

It was also noted that the building was considerably stiffer in the longer direction. Before November 1, 1932, there was little deflection about the minor axis; but during this storm (Table 1, Item No. 103) additional cracking occurred, and the building began to deflect and vibrate appreciably about both axes. After this storm it was noticed that winds of 55 to 60 miles per hr against either of the narrow faces would cause the strain gages to oscillate, but winds below this critical range caused no apparent stress in the steel frame.

Existing Cracks.—In December, 1938, the writer made a visual inspection of existing cracks on several unoccupied floors, including the twenty-ninth, forty-second, and fifty-fifth floors. It was found that the cracks in the floors and walls were more numerous then than in 1933 (five years previous). Inspection of the floors showed prominent cracks extending between column centers in both directions. It is probable that these cracks were caused chiefly by natural shrinkage of the concrete, as they generally averaged about 0.12 in. in width with columns spaced about 20 ft on centers. It was noted, however, that in several places the floor on one side of a crack was more than $\frac{1}{16}$ in. above the level on the other side, and in some cases the maximum vertical displacement was nearly $\frac{1}{8}$ in. There were relatively few cracks in the plastered ceilings; but the plastered partitions surrounding the elevator shafts were seriously cracked in the lower portion of the main tower and cracked to a lesser degree in the upper stories.

Velocity of the Wind.—In studying Table 1, it should be noted that the New York City Observatory in Central Park is nearly 7.5 miles from the U. S. Weather Bureau. The anemometer in Central Park is 62 ft above the ground, but only about 30 ft above the trees. In addition, the park is entirely surrounded by tall buildings averaging approximately 140 ft in height. The U. S. Weather Bureau, near the southern tip of Manhattan, is 454 ft above the harbor, but is near the down-town "skyscraper" zone, and winds from the north, northeast, and east are seriously modified in velocity and direction by these tall buildings. The anemometer on the Empire State Building has a 32-blade rotor which is restrained by helical springs, attached by gears to a self-synchronous motor. When the wind blows the rotor turns through less than 360° and the angle of rotation measures the wind velocity. The anemometer on the Daily News Building is similar to the one on the Empire State Building, but is 30 ft above the roof and may be less affected by the up-draft on the windward side of the building.

Before January 1, 1928, the U. S. Weather Bureau used a four-cup anemometer which gave indicated wind velocities greater than the true velocity. During the next few years, however, a new three-cup anemometer was developed to give more accuracy and, since January 1, 1932, wind speeds published by the U. S. Weather Bureau have been corrected before publication to give true wind speeds. In analyzing wind records it is important to know whether the velocity represents the average for a 1-hr period, a 5-min period, or a brief gust, as there may be considerable difference in these velocities. The velocities obtained at the Empire State Building are averages estimated after watching the anemometer dial for several minutes, but most of the other velocities are averages for a 1-hr period.

Wind-tunnel tests made at the National Bureau of Standards on a model of the Empire State Building indicate that the velocity 15 ft above the observation tower is about 23% greater than the velocity of the approaching wind. The wind velocities recorded in Column (4), Table 1, therefore, are about 23% too high and should be reduced when studying the actual wind pressures on the building. Another factor that should be considered is that during a severe storm the wind velocity 1 263 ft above the ground is undoubtedly greater than the velocity nearer the ground.

TABLE 7.—AVERAGE WIND VELOCITIES GROUPED BY INTENSITY

Observed velocity of wind, in miles per hour	Number of observations	AVERAGE VELOCITY OF WIND, IN MILES PER HOUR*				RATIO OF VELOCITIES COMPARED WITH EMPIRE STATE BUILDING

50 or more	28	59.2	21.0	26.6	29.8	100	36	46	51

* At Empire State Building wind velocities are averages for a brief period of observation, but at the other three observatories wind velocities are averages for a 1-hr period.

The winds in Table 1 were first arranged in six groups, according to velocity, and each group was averaged to obtain the data shown in Table 7. This study shows that the relative wind velocities at the four observatories change considerably as the storms increase in strength. With strong winds, low buildings receive considerable protection from surrounding buildings and the degree of protection is relatively greater during extremely severe storms.

The relation between height and velocity may be estimated from the storm of March 22, 1936, at the top of Table 1, which gives an indicated wind velocity of 102 miles per hr at the Empire State Building. The true velocity of the approaching wind, therefore, was about 84 miles per hr, compared with 71 miles per hr at the U. S. Weather Bureau and 54.4 miles per hr at the New York City Observatory in Central Park (see Table 8).

TABLE 8.—RELATION BETWEEN HEIGHT AND VELOCITY

Location of anemometer	Height above ground, in feet	True velocity of wind, in miles per hour	Ratio
Empire State Building	1 263	84	100
U. S. Weather Bureau	444	71	85
Central Park Observatory	62	54	65

On several occasions the writer has observed flags on various tall buildings flying in different directions with variations in direction as much as 90° at the same instant. In order to study the effect of surrounding buildings on velocity and direction, the winds of Table 1 were grouped by the direction indicated at the Empire State Building and the directions at the other observatories expressed as plus or minus degrees. This study showed fairly consistent differences for each particular direction and indicated that at the three lower stations both velocity and direction of the wind are seriously affected by the surrounding buildings.

On November 1, 1932, three sets of observations were made, as indicated by Items Nos. 100, 101, 102, Table 1. For several hours the wind was exceptionally steady with an indicated velocity of 75 miles per hr from the southeast.

Average		43.4	17.5	22.1	27.7
Ratio		100%	39%	50%	62%

* These points have been omitted from the average because tall buildings apparently shield the anemometer when winds are from these directions.

Just before noon, while the plumb-bob was being observed, the wind suddenly increased in intensity for a few minutes, swung around through south and then steadied at about 55 miles per hr from the west northwest. The exact time of this occurrence is not known, but the total change from an 85-mile southeast wind to a 55-mile west northwest wind probably occurred in less than 3 min. Similar rapid changes occurred on several other occasions and probably account for some of the marked variations in direction noted in Table 1.

Table 9 gives the average velocity of all winds of 30 miles per hr or more, grouped by direction. It shows fairly consistent ratios between the observed velocity at the Empire State Building and the average velocity for a 1-hr period at the other three observatories where recording instruments were used. The velocities shown in the right-hand column are generally about 60% to 65% as great as observed velocities at the Empire State Building, except in certain cases in which the skyscrapers of lower Manhattan shield the anemometer of the U. S. Weather Bureau. Thus, with winds from the northeast the ratio is 33%, and with winds from the east northeast, the ratio is only 21 per cent.

Gust Velocities.—The observations made during this program show clearly that the building not only deflects in accordance with the average wind velocity, but also vibrates due to variations in velocity. During a strong wind the anemometer in the Empire State Building moves back and forth continuously over a range of about 10 miles per hr, but occasionally a vigorous puff or a sudden lull may cause a momentary change in velocity as much as 20 miles per hr above or below the average velocity.

The velocity and duration of these momentary gusts are of considerable importance, as a 40% increase in velocity would cause an increase in pressure of nearly 100%, and if this sudden increase should occur in harmony with the vibration of the structure, the resulting stresses would be much greater than with a steady wind. On the other hand, however, it is quite probable that each gust of wind occurs over a relatively small area and therefore would not change the average pressure as much as indicated by the velocity-pressure equation. To illustrate this point the writer remembers one occasion when an observation was being made on the 5 manometers on the south side of the fifty-fifth floor. Readings had just been recorded for Stations 1, 2, 3, and 4 (Fig. 4) and all were less than 0.50 in. At Station 5 there was a difference of nearly −0.50 in., but while it was being observed, the difference suddenly increased to about −1.50 in. and remained steady at this point for about 10 sec. During this time several quick glances at the other manometers showed no great change at any of the other stations. This would seem to indicate that a gust velocity might be two or three times as great as the average velocity but that the gust might last only a brief time and extend over a relatively small area.

The data in Table 1 indicate that at the U. S. Weather Bureau in New York, N. Y., the maximum velocity for 5-min periods is generally about 17% greater than the 1-hr average. During the New England hurricane of September 21, 1938, the Harvard Meteorological Observatory records indicated an average velocity of 83 miles per hr for 1 hr; 94 miles per hr for $\frac{1}{2}$ hr; 111 miles per hr for a 5-min period; and gust velocities of 173 and 186 miles per hr. The velocity for the maximum 5-min period, therefore, was 34% greater than for the maximum 1-hr period, and the maximum gust velocities were more than twice the maximum hourly velocity.

Wind Pressure.—It is recommended that the data on actual wind pressures be studied in conjunction with the report of the wind-tunnel tests by Messrs. Dryden and Hill.[3] Unfortunately these tests did not include models of the surrounding buildings; but in spite of this the writer feels that their data are more complete and more reliable than the data actually obtained at the Empire State Building.

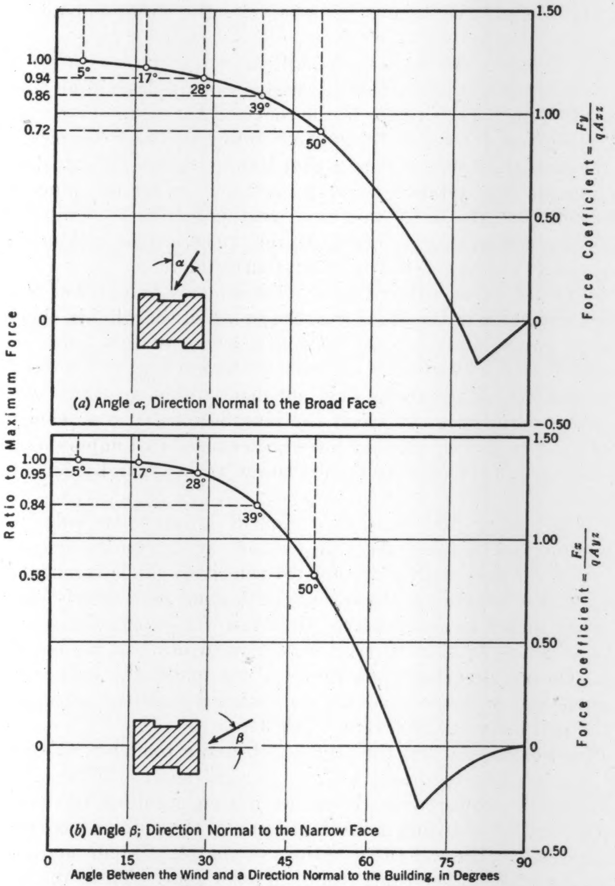

FIG. 25.—RELATION BETWEEN DIRECTION OF WIND AND OVERTURNING FORCE

The Dryden-Hill tests indicated: (*a*) That the greatest overturning moment occurs when the wind blows directly against one face; (*b*) that a suitable value for use in design of tall buildings is 0.0038 V^2, in lb per sq ft (V = wind speed, in miles per hour); and (*c*) that the velocity 15 ft above the top of the observation tower is approximately 23% greater than the velocity of the approaching wind. From the model tests, it was also possible to measure, accurately, the decrease in the overturning moment as the wind becomes more diagonal. The relations between the direction of the wind and the overturning wind force are shown in Fig. 25 and have been used in analyzing the plumb-bob and collimator readings.

The Fire Tower.—The vent shaft built in conjunction with the fire tower acts like an enormous chimney and causes a strong up-draft at all times. This shaft extends from the sixth floor to the roof and has an unobstructed opening of about 40 sq ft at the top. When the building was first completed, the up-draft in the vent shaft was so strong that leakage under the exit doors caused an objectionable high-pitched whining noise. In order to reduce this noise all doors leading to the fire tower were weather-stripped. This reduced the noise but did not eliminate it, and in March, 1933, a light bulkhead was built entirely across the vent shaft at the fifty-fourth floor.

This bulkhead reduced the noise to a satisfactory extent, but when a door was opened anywhere in the fire tower, the sound of the wind in the vent shaft was reduced immediately. After becoming aware of this phenomenon, the writer was able to tell by sound if all doors to the fire tower were tightly closed, and the plumb-bob observations were not made unless all doors were shut, as an open door would seriously affect the plumb-bob. The movements of the plumb-bob, shown in Fig. 12, may have been caused by temporary drafts, due to occasional opening of doors to the fire tower, rather than by deflection of the building.

There is also an up-draft on the exterior on the windward side near the top of the building, and on sunny days the heat of the sun warms one or two faces and the warm air rises with a perceptible velocity. On several occasions the writer has walked around on the seventy-fifth floor, successively opening each window a few inches to note whether the wind was blowing in or out. These observations generally showed a strong outward draft at about 75% of the windows. On one occasion when this test was made, the outward draft was noticed at all except seven windows, indicating a negative pressure on about 91% of the periphery at the seventy-fifth floor.

The Plumb-Bob.—At first the plumb-bob had a tendency to wander in an irregular manner due to drafts within the vent shaft. When all the doors leading to the fire tower were closed, the strong up-draft in the vent shaft produced a peculiar whistling noise; but if any of these doors were opened, this noise decreased greatly and the gyrations of the plumb-bob increased, due to the disturbing effect of the draft from the open door. These difficulties were solved by attaching a pair of oil dampers to the plumb-bob as shown in Fig. 11, and by recording only those observations that were made when all doors to the fire tower were closed.

In making plumb-bob readings the dampers were immersed in oil until the plumb-bob was moving in an ellipse with the major axis about 2 in. long. Small markers were placed on the target to mark the ends of the major and minor axes of this ellipse. As soon as the plumb-bob was observed to make three or

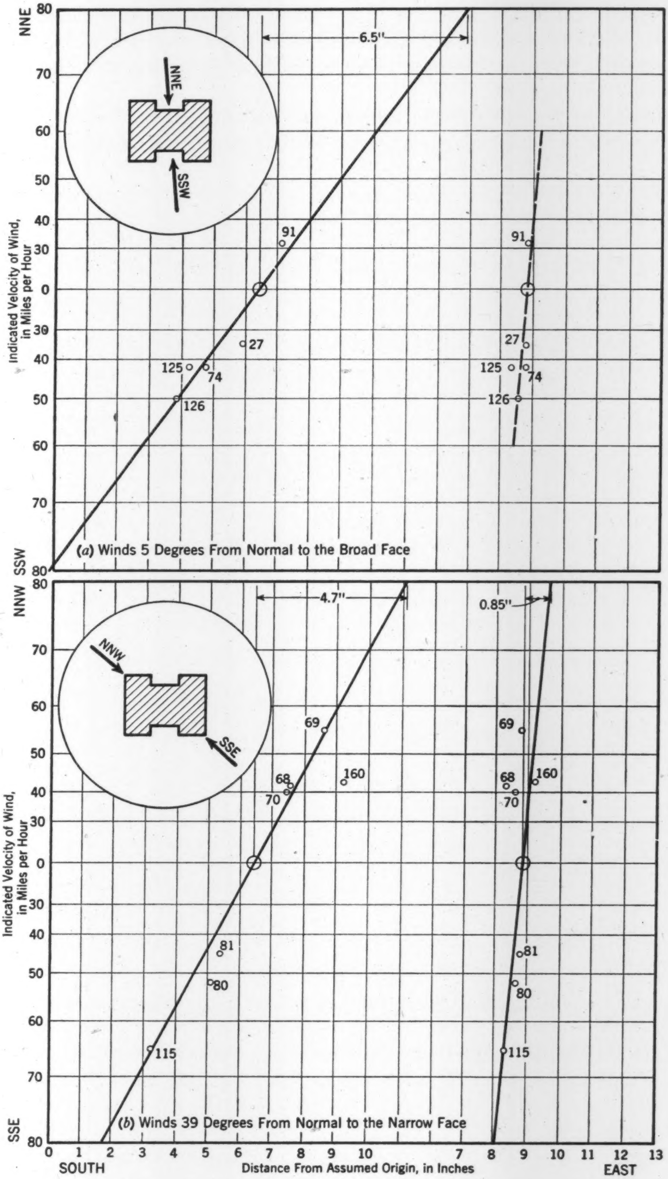

FIG. 26.—DEFLECTION OF THE BUILDING, INDICATED BY PLUMB-BOB

four complete circuits around the same ellipse, the center was observed and recorded. This process was repeated until at least ten readings had been made. These readings were then averaged and entered in the records as a single point for that particular wind.

Deflection of Building from Plumb-Bob Readings.—The deflection of the building was studied by plotting the plumb-bob observations on eight charts, such as the two in Fig. 26. Since the wind force is directly proportional to the square of the velocity, the indicated velocity of the wind was plotted on a parabolic scale so that the deflection curve on these charts will be a straight line. Winds of less than 30 miles per hr were omitted, as the force of these winds apparently was not sufficient to overcome the internal friction in the masonry materials.

* From Fig. 25.

A study of these charts showed that the center of the building is at 6.40 on the east-west axis. The center on the north-south axis is not so well defined, however, due to the fact that the building is much stiffer in this direction, and the plastered partitions and other masonry probably were not seriously cracked in this direction until Storm 109 (see Table 1) on November 9, 1932. The few observations made after this date indicate that the east-west center is probably between 8.70 and 9.00 on the plumb-bob target and an average value of 8.85 has been assumed.

The wind-tunnel tests previously mentioned[3] showed that the greatest overturning moment occurs when the wind is blowing directly against one face of the building, and that this overturning moment gradually decreases as the wind becomes more diagonal (see Fig. 25). The deflections caused by diagonal winds, therefore, can be increased to show the deflection that would have occurred if the wind had been directly against one face of the building. Thus, when the wind is 28° from a normal to the broad face, the overturning force is about 0.94 times as great as for a normal wind and the observed deflection should be divided by 0.94 to obtain the maximum deflection for that particular velocity.

Table 10 was obtained in this manner. This study shows that an indicated velocity of 80 miles per hr directly against either of the broad faces causes a deflection of about 6.5 in. The same wind against either of the narrow faces would cause a deflection of about 2.0 in., which indicates that the moment of inertia about the north-south axis is more than three times as great as about the east-west axis. This ratio may not be a constant, however, as the plastered partitions and other masonry probably carry a large proportion of the wind load when the wind is against the narrow face, and each severe storm may cause further cracking and more flexibility in this direction.

If the indicated velocity at the top of the observation tower is assumed to be about 23% greater than the velocity of the approaching wind, the average deflection of the building at the eighty-sixth floor, as indicated by the plumb-bob, is as follows:

Description	Indicated velocity at the top of the building, in miles per hour:	
	80	100
True velocity of approaching wind, in miles per hour	65	81
Deflection of the building, in inches:		
North-south	6.5	10.2
East-west	2.0	3.1

Deflection of Building from Collimator Readings.—A study of the collimator readings given in Table 5 shows that the center is approximately at 5.6 along the north-south axis. Using this center, the collimator readings have been rearranged in Table 11 to show the average deflection, and the maximum amplitude of vibration for winds greater than 30 miles per hr against either of the broad faces. By using the "force ratios" obtained from Fig. 25(a), it is possible to estimate the probable deflection and vibration that would have occurred with a "normal" wind blowing directly against either of the broad faces.

Columns (7) and (8), Table 11, when plotted, indicate that the north-south deflection of the building is about 6.5 in. with an indicated wind velocity of 80 miles per hr. The average deflection indicated by the plumb-bob and the collimator is in close agreement for north-south deflections. In the east-west direction, however, there are insufficient collimator readings to determine the deflection with any degree of assurance.

In addition to the average deflection, the building vibrates, and the maximum range of vibration, as indicated by the collimator readings, is about 10% greater than the average deflection. This means that an 80-mile wind may cause the building to deflect about 6.5 in. and to vibrate about 7.2 in. about the deflected position. In this case the extreme deflection of the building would be 6.5 + 3.6 = 10.1 in.

Fig. 14 shows graphically the period of vibration of the building as observed with the collimator on November 1, 1932. It shows 104 cycles in about 860 sec, indicating a period of vibration of about 8.28 sec. It is also difficult to understand how a period of 8.14 sec was derived from the data in Fig. 15.

In December, 1938, when the writer last visited the building, the wind velocity was between 40 and 50 miles per hr, and it was possible to hear faint groans as the building vibrated; 28 groans were heard in slightly less than 2 min, timed with an ordinary watch, which seems to indicate that the period of vibration is still about 8.3 sec as measured on November 1, 1932.

* From Fig. 25.

Conclusions.—From the foregoing, the writer advances the following nine conclusions:

(1) The plastered partitions, concrete floors, and masonry walls add both strength and stiffness to the building and carry a large percentage of the wind load. Any theory that ignores this fact is probably so far from the truth that great refinement is not warranted.

(2) The ratio between the stiffness of the building and the stiffness of the steel frame is not constant. It may have been 10 to 1 when the building was first completed and it may still be about 3 to 1. It is quite probable, however, that extremely severe storms will extend the existing cracks and allow the steel frame to carry a greater proportion of the wind load.

(3) After a severe storm, the building does not return exactly to normal. As the wind decreases, the deflection decreases until the frictional resistance of the building equals the restoring force of the deflected materials. The building then remains in this slightly deflected position until the next storm.

(4) The plumb-bob readings show that an indicated wind velocity of 80 miles per hr against either of the broad faces caused a deflection of about 6.5 in.; but the same velocity against either of the narrow faces caused a deflection only one-third as great.

(5) The collimator readings show that the building vibrates about the deflected position. The period of vibration is about 8.3 sec, and the range of vibration is slightly greater than the average deflection. An indicated velocity of 80 miles per hr, against either of the broad faces, therefore, would cause the building to vibrate back and forth over a range of about 7.2 in., and the extreme deflection would be $6.5 + 3.6 = 10.1$ in.

(6) During severe storms the vibration of the building causes groans as the masonry slips on the steel frame, or along cracks caused by previous storms.

(7) There is generally a strong up-draft on the windward side of the Empire State Building above the fifty-fifth floor. This up-draft, combined with the horizontal wind, probably causes a resultant velocity considerably greater than the velocity of the approaching wind. Indicated wind velocities at the Empire State Building, therefore, should be reduced to obtain the true wind speed.

(8) Both the velocity and direction of the wind are seriously affected by surrounding buildings. Low buildings receive considerable protection from surrounding buildings, and the sheltered area on the lee of a building is relatively greater during more severe storms.

(9) In New York City, during a very severe storm, there is considerable difference in velocity at points 100 ft, 500 ft, and 1 000 ft above the ground. A rough estimate indicates that simultaneous velocities at these three levels might be 55, 70, and 80 miles per hr. The corresponding wind pressures, therefore, would be about 20.9, 26.6, and 30.4 lb per sq ft, respectively, at elevations 100 ft, 500 ft, and 1 000 ft above the ground.

J. CHARLES RATHBUN,[51] M. AM. SOC. C. E. (by letter).—This paper has been fortunate in having so many able discussers. As many of them have been interested actively in this or a similar problem they have been able to suggest a number of related phases that should be given study. The most outstanding one is that of building vibration.

Strength and stiffness are two entirely different characteristics of a structure, as emphasized by Mr. Coyle and Professor Morris. This paper has been primarily concerned with the lateral loads on a building although it has taken into consideration both of these other questions to a considerable extent. To study the wind effects properly one must consider not only the physical characteristics of the building but also the effect of vibration on the tenants. It was considered unwise to expand the scope of this investigation into this latter field, although the value of it was recognized. Mr. Coyle has collected considerable data on the subject of vibration in various buildings and has given it careful study.

---

[51] Associate Prof., Civ. Eng., Coll. of the City of New York, New York, N. Y.

The writer agrees with Professor Morris that extreme refinement of mathematical calculations is unwarranted but that some theory of stress distribution for lateral stability is necessary in designing buildings. A continued study of the problem should reveal better theories that will enable the engineer to anticipate the action of his building under all conditions of loading, without increasing the labor of analysis unreasonably. The writer wishes to emphasize that he did not suggest that the fact—that the architectural clothing adds to the strength of the building—should be taken into consideration in its design. Both conclusions (8) and (9) demonstrate this point; and Professor Morris emphasizes it. The third sentence of Mr. Skinner's discussion is not at all in accord with the writer's opinion; nor does it seem to follow from the findings. In fact, his account of the gradual transfer of load from the masonry to the steel leads to the opposite conclusion.

Mr. Fleming's discussion is valuable particularly as he gives numerous references on this question and related problems. He quotes the report of the British Research Committee[52]: "In a large class of steel-framed buildings * * * the steel work is thus relieved of the responsibility of resisting wind shear." This idea should be studied carefully and the character of the building noted. For the tall steel building—the skyscraper—the writer feels that the steel should carry the responsibility of the wind load and lateral stability of the structure, even if the load is partly taken by the masonry.

It is true, as Mr. Shearwood suggests, that the data obtained from the Empire State Building show that the problem is far too complicated to be formulated by simple uniform horizontal loads and methods of analysis. In design the engineer endeavors "to distribute, exactly, indeterminate stresses induced by indeterminate forces." The writer hopes that nothing in his paper will lead to the idea that this is not good engineering practice. Of course, formulas must be followed with judgment and experience, not just as a guide. Engineers with sound judgment and broad experience may be able to design safely but most of them should not be encouraged to dispense with accepted methods which in the past have produced safe structures. If the experience and study of the specialists have decided that stresses obtained by conventional methods should not be exceeded is it wise for the Profession to violate these suggestions? In cases where they are sure the previous study does not apply, or where it has been improved upon, a special investigation should be made and the result applied in a conservative manner.

The writer believes (see fifth paragraph in Part II, under "Introduction") that it is probably wise to ignore the strength of the masonry until, as Mr. Shearwood suggests, further investigation of this problem is made.

Mr. Jacobsen has stated the fact (as has the writer preceding and following Equation (1)) that T and W are ratios of time and weight between the building and the model. The facilities for observing the period of vibration by means of the collimator are available for future use. It is planned to make checks from time to time on the building to note if a gradual change takes place in its period of vibration.

---

[52] Third and Final Report, British Steel Structures Research Committee, Dept. of Scientific and Industrial Research, 1936.

It is true that Equation (20) can be written without derivation as it is quite simple. The previous equations were given so that one might note the approximations involved and the effect of these approximations on the validity of this equation. The effect of the walls was omitted because the scope of the study was a comparison between the frame of the building and the model. The results of this study were compared with the actual building and the difference was attributed to the stiffness due to the walls.

The columns of the Empire State Building rest on solid rock whereas the columns of the model are anchored to steel bars. Therefore, both are quite rigid and have little effect in destroying the similitude between model and building frame.

The writer agrees with Professor Castleman that more data of this nature should be gathered. There are serious difficulties, however. It is seldom that the owner of a building is willing to allow an intensive study of his structure to be made and published. Furthermore, the gathering of these data, their interpretation, the equipment necessary, and its installation, are very expensive.

The writer feels, definitely, that the data obtained from wind tunnels by a skilled observer and under laboratory conditions are most valuable. The data are obtained under controlled conditions and so can be understood much better than those obtained from observations on a building. They are two entirely different sets of data but the reason for the differences between them is worthy of study. The local conditions that tend to break up the wind currents is only one factor, although an important one. The work of Messrs. Dryden and Hill is most valuable and the data therein should be compared with those obtained on the building itself.

The law of variation of pressure with distances from the ground has not been formulated as suggested by Professor Castleman. As can be seen from the data of this paper it is quite erratic. The observations given by Mr. Skinner in his Conclusion (9) are only one set of many and should have no more weight than the other items of Table 2. They certainly do not warrant the authority that is due a "conclusion."

The only objection the writer sees to adding the term suggested by Professor Castleman to Equation (18) is that it increases the length of the equation. When it was omitted it was thought the numerical value would be very small.

The fact that the temperature effect on the building is negligible should not lead one to generalize. The construction of the building, as well as the efficiency of the insulation around the frame, will have much to do with this effect. It was examined into, and recorded, largely to show that it was not the cause of the plumb-bob's failure to return to a fixed center.

Professor Wilbur discusses the deflection index and its importance. The data taken from the Empire State Building should be of considerable value in determining this index.

Mr. Spellman suggests that "in some instances a substantial saving could be attained safely by omitting wind-bracing." This is done in some cities where the ordinance allows one to design buildings less than a certain height without allowing for wind loads. To extend this practice to the top part of tall buildings is an idea of questionable value and one not encouraged by the data of this paper. If there are substantial wind loads the writer feels that they should be provided for in the steel.

It was particularly gratifying to note that the late Mr. Molitor[53] accepted the percentage added to the rigidity by the masonry as obtained by the writer. This value may vary between wide limits even in the same building while the materials are becoming adjusted to each other. He, like the writer, and several of the contributors to this paper seemed to approve the present method of stress analysis and assumed lateral loads. To date the results have proved satisfactory. The tests on the Empire State Building seem to indicate that 20 lb per sq ft is not too great and since there have been few if any failures due to wind it is not too low; and so, until better methods of loading, analysis, and design are discovered, the present method should not be considered outmoded.

Mr. Gray's observation of the fog phenomenon gives some idea of the action of the wind currents about the building.

Mr. DeBlois has expressed an interesting idea relative to the damping effect shown in the model data; and the curves viewed from this standpoint show this effect clearly. The writer was unable to devise any way of measuring this same phenomenon on the building and so could not use it in his paper.

Mr. Smith's plots of wind forces against their direction are very enlightening and, to some extent, show the general direction of the wind in New York, and also the effect of the neighboring buildings. He also calls attention to irregularities in the manometer and extensometer readings. These were noted before submitting the manuscript but it was decided that their omission would tend to lead to a false sense of accuracy.

The extensometer rods were close to the columns and were covered with the same insulating material. Thus the elongation due to temperature will be the same for both rod and column and the reading will not be affected. It has been shown by the test on building deflection that the temperature effect is very slight.

Mr. Bergman emphasizes the importance of rigidity in a building and that the designer is working between limits. As the writer has stated, this is a problem that could be studied to advantage by the Profession.

Mr. Gottschalk's suggestion that there should be more simple methods of obtaining the information about masonry stiffening than by models is one that it is hoped will be acted on and one which will lead to studies on buildings other than the Empire State. The difficulties already outlined by the writer make it probable that not many such studies will be made.

Mr. Skinner is to be commended that his interest in the problem induced him to make further observations after field work was considered finished and some of the instruments had been removed from the building. In many cases, however, his discussion gives an entirely erroneous impression due to an overemphasis on data that are considered by the writer to be of but little moment.

---

[53] David A. Molitor, M. Am. Soc. C. E., died on September 8, 1939.

This is particularly true of the wind currents in the fire tower and the creaking of the building during a high wind. The actual data on which Mr. Skinner bases his findings were available to the writer when the paper was written.

Mr. Skinner's comments relative to air currents should not lead one to discredit the work of the plumb-bob, and the findings shown in Fig. 12. When the writer first installed this bob it was found necessary to damp it, of course. After this all recorded readings were made with great care and accuracy. Sources of error such as temperature, wind currents, etc., were studied and taken into consideration. At the writer's suggestion, one of the observers made a study of the accuracy of his readings and found that they had a probable error of less than one-eighth inch. This is more accurate than the collimator readings. The eight charts similar to Fig. 26 were a part of a study made during the early part of the data-gathering period. The idea was abandoned because it was shown that the plasticity of the building is considerable and therefore the center of rest is of no importance.

The creaking mentioned by Mr. Skinner is a very usual phenomenon with structures when new and it would have been surprising if this building had proved an exception. In bridges it is not noticeable because of other noises when the load is being applied; in new occupied buildings this is also true to a limited extent but in new ships and vacant buildings it is noted often. That an observer who is watching for data should note it, is as it should be; that he should pick up the period of vibration from the sound is most interesting and Mr. Skinner is to be congratulated on using this information to advantage. That the noises should be classed as groans is incorrect and misleading. As he stated, when the building reached structural adjustment the sounds abated, just as one would anticipate.

The writer has investigated the question of the partitions that are "seriously cracked" and finds that no reports of any serious, dangerous, or even prominent cracks in partitions or floors have been made to those responsible for the building. As the building is composed of many materials, some weak in tension (concrete and plaster), it would be surprising if some cracks did not appear during the first winter. However, these are very minor and the writer did not consider them of any structural significance except to show adjustment of stress. The partitions are not a part of the working structure and there are no cracks in the floors due to wind.

To be complete, Mr. Skinner's attempt to correlate the observations of the four New York stations should indicate the spread of the data as well as their averages. There are so many factors that enter into this problem that a simple average does not give the true picture; nor can it be applied to one storm, or indicate the maximum velocities at the several stations and their ratios to each other.

The writer agrees with Mr. Skinner and the several other discussers that the work of Messrs. Dryden and Hill is of great value and should be studied by all those interested in the problem. Much of Mr. Skinner's discussion is mainly a repetition of the data, conclusions, and ideas expressed in the paper and with these, of course, the writer agrees. He has tried to give full credit for all of the ideas that were given by those associated with him in the work. However those employed in gathering data were too numerous to mention by name.

Mr. Skinner closes with nine "conclusions." Conclusion (1) is covered by the writer's Conclusion (8). His last sentence depends upon the meaning of "great refinement." In Conclusion (2), the figures given should have been substantiated by data. If they are only a guess the writer questions the wisdom of having given them. His first sentence is a contribution to the subject. Conclusion (3) is a repetition of the writer's Conclusion (2). Since the plumb-bob and Fig. 12 were the sources of the necessary data, and Mr. Skinner questions the accuracy of these, one wonders how he arrived at this conclusion. The writer questions the accuracy of Conclusion (4) but considers it of little importance. The data from which Conclusion (5) was drawn is probably Table 5. As the vibration and deflection are not simply related phenomena the writer questions the wisdom of generalizing from the data. As the data are available the reader can decide this matter. As for Conclusion (6), a normal amount of creaking and grating can be heard by those who are listening for it but this is not a structural defect. The idea of the masonry slipping on the steel frame is interesting but not probable unless data not published bear it out. The squeaking of joints in metallic partitions has been reported. The building, definitely, does not groan during a high wind. Conclusions (7) and (8) were fully covered by the writer's paper. The information in Conclusion (9) was based on one of the many observations, selections from which were taken to form Tables 1 and 2. The findings scarcely warrant a conclusion, however, as it was only one set of readings.

Mr. Skinner's discussion is full of "food for thought." His observations on the gradual increase of the sensitivity of the steel are of great interest. It is unfortunate that quantitative data were not secured. In many cases his overstatement of the data has led to an incorrect impression but it is probably for the best that a different point of view has been advanced for the reader to consider. The writer has tried not to draw conclusions from general averages of very erratic data but where Mr. Skinner has done so the reader can judge each case on its relative merits since he has all of the pertinent data.

In closing the writer wishes to thank all those who have contributed, either by supplying funds and physical facilities, collecting data, making suggestions, or discussing the paper. It is hoped that future studies will enable the designing engineer to work with greater exactness in predicting the stresses due to wind on his structure because of the ideas and data given in this paper and its discussions.

ANALYSIS OF RUN-OFF CHARACTERISTICS

By Otto H. Meyer,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Victor H. Cochrane, Bertram S. Barnes, LeRoy K. Sherman, Richmond T. Zoch, Merrill Bernard, Franklin F. Snyder, W. G. Hoyt, C. O. Clark, C. S. Jarvis, Howard M. Turner, and Otto H. Meyer.

Synopsis

An analysis of the characteristics of run-off hydrographs is outlined in this paper, which proposes a revision of current methods for the determination of stream flow from rainfall. It is shown that a continuous rain of constant intensity produces a hydrograph of characteristic shape for any drainage area, and that this shape and the length of time until the run-off becomes constant (time of concentration) are functions of the shape and size of the drainage area. A method of constructing a hydrograph resulting from rain of duration less than the time of concentration is proposed. Based on this analysis, methods have been devised for determining hydrographs for areas lacking in run-off records, from the records of other areas similar in characteristics but different in size, and for the construction from rainfall data of hydrographs for storms or series of storms of varying intensity.

Unit Hydrographs and Distribution Graphs

Hydrographs resulting from isolated storms have long been known to have characteristic shapes. LeRoy K. Sherman, M. Am. Soc. C. E., found that for any drainage area all hydrographs resulting from isolated storms of a certain duration had approximately the same length of base, and that when reduced proportionally to correspond to the same volume of run-off they had very similar shapes.[2] He proposed the "unit hydrograph," or the hydrograph resulting from a 1-in. run-off from precipitation occurring in a unit of time (usually 24 hr). When its ordinates are multiplied by the inches of run-off from any storm of unit duration, this unit hydrograph gives the hydrograph resulting from that storm.

Note.—Published in November, 1938, *Proceedings*.

[2] *Engineering News-Record*, April 7, 1932.

Merrill M. Bernard, M. Am. Soc. C. E., proposed a "distribution graph," in shape similar to the unit hydrograph, but representing, by its ordinates, percentages of the total run-off from a storm, or the proportional distribution of run-off with respect to time.[3] The distribution graph is derived by dividing the ordinates of the unit hydrograph by the total volume of run-off, as indicated by the area under the graph. A refinement of the method of using a single actual hydrograph to determine the distribution graph is to compute distribution graphs for a number of storms, plot them together, fitted as well as possible to each other, and draw a mean graph, thus producing the most probably representative distribution graph.[4]

A method of constructing the composite hydrograph resulting from a series of rains, or rains lasting through several units of time, has been developed and is in general use.[4] The procedure is to compute the hydrograph resulting from the rain in each unit of time, and to add the resulting hydrographs directly. The composite hydrograph thus constructed will fit the actual observed hydrograph fairly closely.

At best, stream-flow records are meager, and hydrographs are frequently required for points at which no gages have been established. Under such circumstances it is required to determine an approximate distribution graph by transposition from another drainage area or from another part of the same area. Mr. Sherman has proposed a method of determining a unit hydrograph for any size of drainage area from the known hydrograph of a drainage area of similar characteristics.[5] This method (based on the principle that all dimensions of similar areas vary as the square roots of the areas) is, in brief, to increase or reduce the ordinates and abscissas of the unit hydrograph in proportion to the square roots of the respective drainage areas. This similarity of drainage areas applies particularly to slope, nature of the topography, extent of vegetation, and distribution of tributaries. For the relation to hold requires that the mean velocity of the water remain approximately constant through the length of the water-shed. However, the velocity of flowing water, which determines the length of the unit hydrograph, depends not only on slope (which the transposition leaves unchanged although small drainage areas have steeper slopes than large ones), but also on hydraulic radius and stream-bed roughness, which vary with the size of the drainage area. The velocity, therefore, should not be assumed to be constant. It is thus apparent that reliance cannot be placed on the foregoing method. An attempt was made by the writer, using this method, to determine hydrographs at successive points on the Suncook River in New Hampshire, with indifferent success. It is true that each of the hydrographs constructed was, in itself, a reasonably good approximation, but comparisons between them failed to give the information required in this case, which involved the routing of natural and reservoir-modified flood hydrographs. Obviously, a real necessity for a more refined method exists.

Defects similar to the foregoing exist also in the following formulas proposed by the Committee on Floods,[6] of the Boston Society of Civil Engineers:

---

[3] "An Approach to Determinate Stream Flow," by Merrill M. Bernard, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 347.

$T \propto \sqrt{M}$; and,

$$Q_p = C_f \sqrt{M} R \qquad (1)$$

in which M is the drainage area, in square miles; T is the total flood period, in days; Q is the peak discharge, in cubic feet per second; C_f is a flood coefficient, and R is the total run-off in inches above the base flow. These relations, involving, respectively, the abscissas and ordinates of the hydrograph, are in effect the same as those assumed by Mr. Sherman. According to the report of the Committee, these relationships, which are only approximately borne out by actual observations, are based on the assumption that the drainage area involved is rectangular and of uniform slope, like a shingle on a roof, and without any well-defined channels.

Analysis of the Hydrograph

It is well known that run-off is not a function of rainfall alone, but involves such factors as infiltration, evaporation, and surface pondage. The relationship between rainfall and the actual flow into streams is still the subject of much discussion, but probably it will be generally conceded that after a short time lag the run-off will be approximately proportional to the rainfall. Rainfall intensities vary considerably, and uniform, continuous rainfall is actually an unknown phenomenon. For these reasons, and because fluctuations in the intensity of a rain of considerable duration have only a minor influence on the shape of the hydrograph, it is assumed permissible to treat the run-off as a constant percentage of a uniform rain. Rainfall rates and percentages of run-off are assumed constant, therefore, unless otherwise specifically stated. It is also assumed that ground-water flow is separable from flood flow, and, consequently, it is assumed to be separated and is not mentioned in the analysis of flood flows. Uniform distribution of rainfall over the entire drainage area is also assumed, although it is understood that this condition is never realized, and is only approached on small water-sheds; in actual cases the hydrograph is not expected to vary greatly in shape from one produced by rain of uniform distribution.

Assuming a uniform, continuous rain, the run-off passing any point on the stream will increase as water from more distant parts of the drainage area comes to the point of measurement, reaching a maximum and becoming constant when water from the farthest extremity of the drainage area arrives. This time, until water from the most distant part of the drainage area reaches the gage, is known as the time of concentration.

If, after the run-off has become constant, the rainfall ceases, all water in surface detention soon runs off into the stream beds, soaks into the ground, or evaporates. As the streams then have no source of replenishment other than ground-water flow, which has been eliminated from consideration, all flow thereafter must come from depletion of the water in channel or valley storage. The run-off then follows a descending curve which W. W. Horner, M. Am. Soc. C. E., and F. L. Flynt, Assoc. M. Am. Soc. C. E.,[7] found to follow the general equation:

---

[7] "Relation Between Rainfall and Run-Off from Small Urban Areas," *Transactions*, Am. Soc. C. E., Vol. 101 (1936), Equation (2), p. 151.

$$Q_d = \frac{Q_m}{K^{t-t_l}} \qquad (2)$$

in which Q_d is the discharge, in cubic feet per second, on the descending limb of the hydrograph; Q_m is the maximum or peak discharge, in cubic feet per second; K is a constant; t is the time from the beginning of the storm, in minutes, corresponding to any Q_d; and t_l (time lag to peak) is the time corresponding to Q_m. A similar expression was derived by Mr. Richmond T. Zoch.[8] The writer found:

$$C_1 - t = C_2 \log Q \qquad (3)$$

in which C_1 and C_2 are constants applicable to a particular drainage area; t is the time from the beginning of the storm, in days; and Q is discharge, in cubic feet per second. It may be seen that these are different forms of the same function.

An investigation of the characteristics of this storage run-off function shows that the discharge at any time subsequent to the peak is a direct function of the peak discharge, and that the percentage of the storage yet to run off at any time, and the ratio of the discharge at that time to the peak discharge, is constant irrespective of the magnitude of the storm. As the hydrographs of greater storms yet lie entirely above those of lesser storms this should reconcile the two schools of thought, one of which claims that the length of base of the hydrograph is independent of the magnitude of the storm, and the other of which states, apparently conversely, that the larger the storm, the longer the hydrograph will be. The length of base is actually infinite, but the time until the ordinates have receded to some particular infinitesimal proportion of the peak ordinate is approximately constant for any drainage area.

Another corollary to the logarithmic expression for storage run-off is that discharge is directly proportional to the volume remaining in storage. For example, Equation (3) may also be expressed as,

$$Q = e^{\alpha} \qquad (4)$$

in which e is the base of Naperian logarithms, and

$$\alpha = \frac{C_1 - t}{C_2} \qquad (5)$$

The volume, V_s, remaining in valley storage at any time is equal to the area under the curve and to the right of the point corresponding to the time, or,

$$V_s = \int_t^{\infty} e^{\alpha}\, dt = -\, C_2 \left[e^{\alpha}\right]_t^{\infty} = C_2\, e^{\alpha} = C_2\, Q \qquad (6)$$

A convenient name for the part of the hydrograph occurring up to the time of concentration is "concentration curve." Although it governs the shape of the "storage curve" (or descending limb of the hydrograph), the shape of the concentration curve is itself dependent on several factors. One of these is the "histogram" of the drainage area, a function of the shape of the drainage area, and the arrangement of tributaries. A histogram is a graph on which stream-bed, or "thalweg," distances from a point down stream are expressed as abscissas; and drainage basin widths, or, rather, areas per unit of distance, are expressed as ordinates. If the histogram is altered by substituting for distances the time required for water to travel to the point of measurement, its integral will then become the concentration curve. In other words, the increase in ordinate of the hydrograph per unit of time is proportional to the additional area, water from which first reached the point of measurement during that unit of time. The time of travel itself is dependent on stream velocity. The velocity varies widely, from place to place on the same stream, but was found for the Mississippi River to fluctuate about a value approximately proportional to the one-fourth power of the distance from the head-waters. The time of travel from the head-waters to any point will then be proportional to the three-fourths power of the distance because, if $\frac{dx}{dt} = x^{0.25}$; $dt = x^{-0.25}\,dx$; and, $t = \frac{4}{3}\,x^{0.75}$. It follows, then, that for similar drainage areas the time of concentration may be expected to be proportional to the three-fourths power of the length, or approximately proportional to the three-eights power of the area.

---

[8] *Monthly Weather Review*, September, 1934.

It is now time to define a new concept, which will be referred to as the "basic hydrograph." This is the hydrograph resulting from a uniform rain with a duration equal to the time of concentration. This hydrograph has for its rising limb the concentration curve and for its falling limb the storage curve. There is a sharp break at the top. This break has actually been found on continuous gage records (see Fig. 1), although storms of sufficient duration to produce actual basic hydrographs on large drainage areas are quite infrequent, and the supply of data available from water-stage recorders at any place is small.

When a storm with a duration less than the time of concentration occurs, the hydrograph has a somewhat different shape, as shown by Figs. 1 and 2. A method of deriving the hydrographs of storms of shorter duration has been developed. It may also be used to synthesize the basic hydrograph from one produced by a storm of a known shorter duration. The storage curve has been described as conforming to Equation (3). This is only approximately true. Actually, the storage curve is the sum of a theoretically infinite number of curves, each of which conforms closely to the equation, and each of which expresses the run-off from an element of area at a certain time-distance from the point of measurement. A convenient, fairly close approximation is to group the run-off from the area, water from which first reaches the point of measurement within a certain unit of time, and determine the constants of the equation for that group. The unit should be about one-tenth the time of concentration, or less. The smaller the unit the better will be the definition of the curves. In practice, the equation itself is not determined, but only the ratio, λ, of two ordinates one unit of time apart; this is a constant for the particular equation. This ratio (see Appendix I) is found to be:

$$\log_e \lambda = -\frac{h}{V_s} \qquad \text{(7)}$$

As V_s is approximately equal to h times the mean time, t_m, it follows:

$$\log_e \lambda = \frac{-1}{t_m} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which h is the difference between the ordinates on the concentration curve at the beginning and end of the unit of time; and V_s is the area between the corresponding abscissas and to the left of the concentration curve, or the volume of run-off from the corresponding area remaining in valley storage, as shown by Fig. 3. As this is the volume of run-off that has not appeared at the gage by the time of the cessation of the storm, it must be the volume under the storage curve also. Successive ordinates on the storage curve are found by multiplying each ordinate in turn by the ratio, λ. This ratio is determined for each unit of time until the time of concentration.

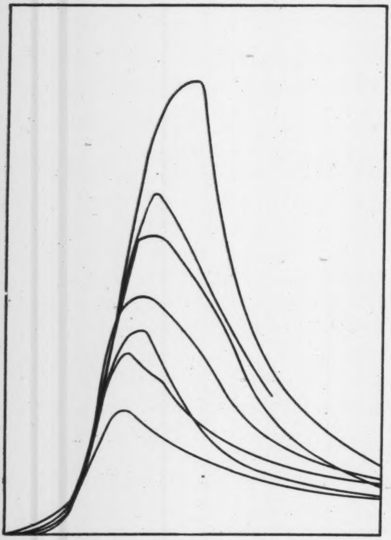

FIG. 1.—GROUP OF HYDROGRAPHS OF PEMIGEWASSET RIVER, AT PLYMOUTH, N. H., REDUCED TO COMPARATIVE SCALE

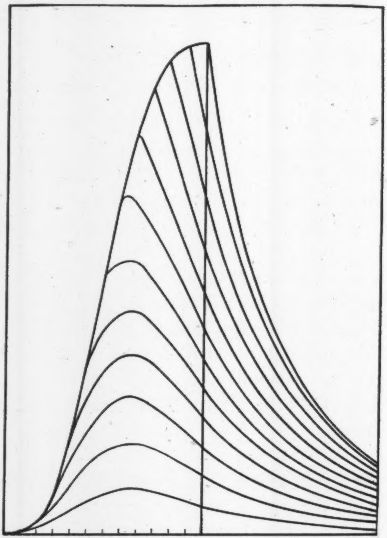

FIG. 2.—HYDROGRAPHS FROM STORMS WITH DURATIONS OF SUCCESSIVE TWELFTHS OF TIME OF CONCENTRATION COMPUTED FROM ASSUMED BASIC HYDROGRAPH

The hydrograph for a storm of any duration will follow the basic hydrograph until the cessation of the storm. At the next unit of time the ordinate will be the sum of the quantities, h, for the preceding units of time, each multiplied by its respective value of the ratio, λ, plus the h-value for the last unit of time multiplied by the ratio of actual run-off volume from its corresponding area to its V_s (which is the ratio of the duration of the storm to the mean abscissa for the unit of time). This last-mentioned multiplication is necessary so that the volume under the corresponding sub-storage curve will be equal to the actual run-off volume available. The following ordinates are the sums of all preceding subordinates multiplied by their respective ratios, plus the h-value for the last unit of time treated as in the foregoing text. After the time of concentration is reached this becomes the sum of all the preceding subordinates multiplied by their respective ratios. A sample computation is shown by Appendix II.

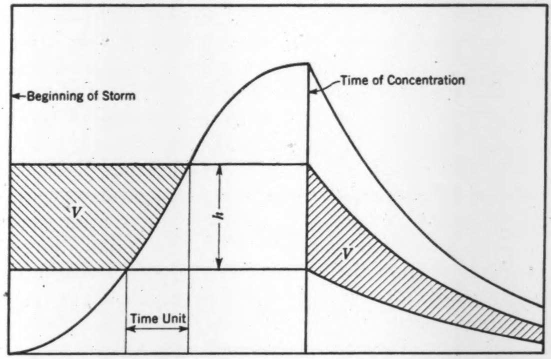

FIG. 3.—VALLEY STORAGE AND SUB-STORAGE CURVE FOR A TIME UNIT

The basic hydrograph may be synthesized from one resulting from a storm of known duration by a reversal of the foregoing process. The height of the peak will be the area under the known hydrograph divided by the duration of the storm, as the peak run-off rate is equal to the rainfall rate multiplied by the percentage run-off. The basic hydrograph will follow the known hydrograph until the cessation of the storm. The aforementioned ratios may be determined in advance, since they can be reduced (as shown) to functions of time. The subordinates for time units previous to the cessation of the storm are treated as described in the foregoing text, and their sum is subtracted from the corresponding ordinate of the hydrograph. The difference is divided by the ratio of the duration of the storm to the mean abscissa of the unit of time. This quotient is added to the last ordinate of the basic hydrograph to give the following one. This procedure is followed until the subtraction gives a negative result. At this point, the ordinate should have reached the maximum previously computed. The storage curve, taken as the sum of all sub-storage curves, then follows.

TRANSPOSITION OF HYDROGRAPHS

As many engineering problems require hydrographs at points where no stream-flow measurements have been taken, some method of transposing hydrographs is necessary. The method proposed by Mr. Sherman, according to which the ordinates and abscissas of the unit hydrograph vary with the square root of the area, has been discussed. Unit hydrographs derived by this method will be correct for total volume of run-off, of course, and will lie within reasonable limits of variation in peak run-off rate; however, they will be subject to considerable error in time of concentration and shape. For several positions on the same stream these hydrographs cannot be used comparatively.

In the course of flood-control studies of the rivers of Maine and New Hampshire, under the United States Engineer Department, it was found necessary to devise some more consistent method of transposing hydrographs. Under the pressure of time, a detailed study being impossible, Mr. Ralph Reinhart, of the Engineer Department, constructed a set of curves based on a large number of distribution graphs which had been prepared by the writer. These curves (shown in Fig. 4) each represent the percentage of the total run-off from a storm of one day duration for one of the first six days of run-off, plotted against drainage area. Each sheet, representing some particular day, contained four curves, representing four groups of drainage area types. It became possible, with experience, to pick the applicable curve after examining topographic maps of the drainage area in question. Each day's proportion of the run-off was then taken from the proper sheet. Only seven sheets were prepared, as the remainder of the hydrograph could be computed quickly by means of the storage curve formula. (The percentage for the seventh day is not shown in Fig. 4.) No attempt has been made to define, exactly, the topography falling in each group, as such an attempt would only be misleading; however, topography producing rapid run-off will fall in a group having a high rate the first few days, and *vice versa.* To determine the run-off distribution for any type of drainage area it will only be necessary to derive the distribution graph for a similar area having run-off records, plot the daily distribution percentages, and find which set of curves fits best. A set of curves of this type is very useful where a large number of hydrographs of a large number of drainage areas is required, and time or the budget does not allow a more refined method.

Certain situations arise where a high degree of refinement in hydrograph computation is required. An example of this would be the investigation preceding the construction of a large flood-control project. In such a case, particularly if hydrographs at various points on a stream are required, Mr. Sherman's transposition does not have a sufficient degree of precision. The aforementioned set of curves (Fig. 4) gives comparable hydrographs for successive points on a stream, but cannot be relied upon for peak run-off rates. A transposition of the basic hydrograph is then the best solution. The basic hydrograph is used in preference to the unit hydrograph because the relation between two basic hydrographs is a function of type and size of drainage area only, whereas the relation between two unit hydrographs involves the ratio of the time unit to the time of concentration, which is not the same for different sized drainage areas. The two unit hydrographs may vary greatly in shape, therefore, whereas the two basic hydrographs would be very similar in shape.

The transposition of the basic hydrograph of one drainage area to another similar area is very simple. The histograms of similar areas are similar, and their concentration curves are very nearly similar. The time of concentration, as shown previously, is approximately proportional to the three-fourths power of the length of the stream, or the three-eighths power of the area. It is pref-

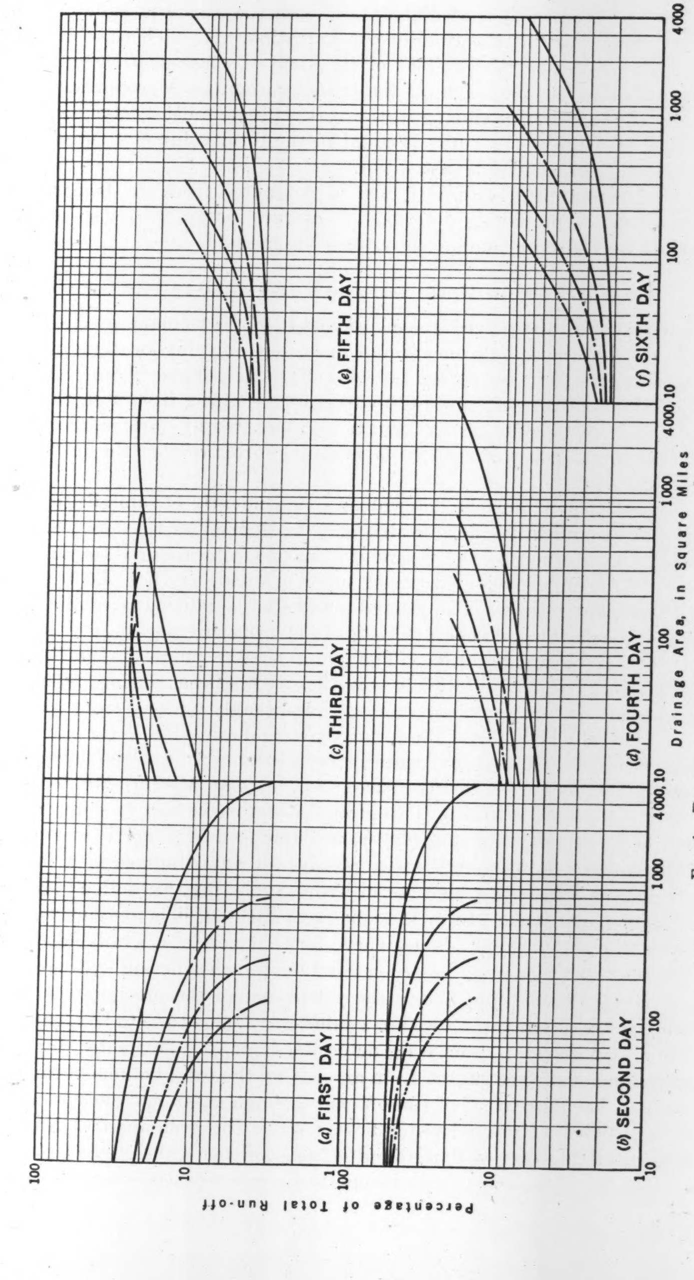

FIG. 4.—DISTRIBUTION PERCENTAGES ON SUCCESSIVE DAYS OF RUN-OFF

erable to use the length if it is available; otherwise the area will suffice. All abscissas will then vary as the time of concentration. As a check, the area under the curve must be the product of the time of concentration and the maximum ordinate. As the height of the basic hydrograph is proportional to the intensity of the storm producing it, the vertical scale must always be such that the total area under the curve is equal to the total volume of run-off; it needs no special treatment in transposition.

If a unit hydrograph is desired it can be computed from the transposed basic hydrograph, as previously described. Distribution graphs for storms of any durations may also be computed by the same method.

Composition or Reconstitution of Hydrographs

The purpose of all the procedures mentioned herein is to make possible the construction of hydrographs from rainfall data, not only for locations where gaging stations exist, but for others as well. For this purpose there must be available methods of constructing the hydrograph resulting from a succession of storms of various magnitudes and durations, separated by various intervals, these methods making use of such tools as unit hydrographs or the proposed basic hydrographs.

One element of flow must be determined independently of rainfall; that is, the "base" or ground-water flow, which may be defined as that part of the run-off which is absorbed by the ground during precipitation or thawing, and which, after traveling varying distances under ground, reaches the beds of streams at some later time. The ground acts as an equalizing reservoir, and the ground-water flow has no characteristics to identify any part of it with any particular period of precipitation. The ground-water curve is that curve which is approached asymptotically by the hydrograph during intervals between storms. It follows an annual cycle, remarkably uniform from year to year. It is generally high during the spring thaws and rains, low in the summer, a little higher in the fall, and low again in the winter. An example is offered by the ground-water curves for five successive years at Mercer, Me., on the Sandy River, shown in Fig. 5(*a*). This ground-water curve may be determined as a mean over several years, and plotted as cubic feet per second per square mile. It may then be used very satisfactorily, for any drainage area in the general region, as a base to which storm hydrographs may be added. If the hydrograph of a particular storm is to be reconstituted, it is obviously preferable to use the actual ground-water curve for that period, if available.

Another element that must be pre-determined in constructing hydrographs is the percentage of run-off. This is the percentage of the precipitation that appears in the streams as run-off within a sufficiently short time to be identified with a particular storm. It may be determined for any storm by dividing the total volume of surface run-off from an area by the total volume of rainfall on that area. The percentage of run-off goes through an annual cycle remarkably similar to that of ground-water flow. When the ground-water level is high the absorptive power of the ground is low, and the percentage of run-off is high. It is, in fact, almost proportional to the ground-water flow. An example of this cycle is given by Fig. 5(*b*), which is the percentage of run-off for the same location and period covered for ground-water by Fig. 5(*a*). Percentages greater than 100 are caused by melting snow.

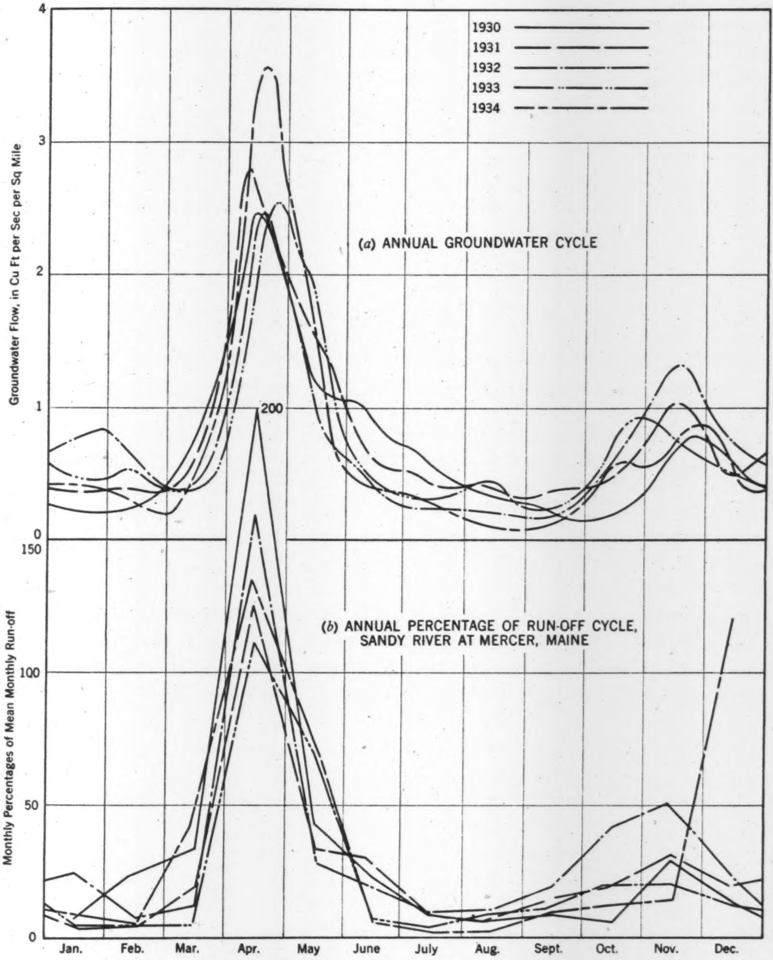

FIG. 5.—CURVES OF SANDY RIVER, AT MERCER, ME.

It is clear that in reconstituting a hydrograph from rainfall the time of year must be known in order to have the correct base flow and the correct run-off percentage for each storm. In composing the hydrograph resulting from an assumed storm, the time of year must be assumed also. Each day's rain must be multiplied by the percentage of run-off for that date, and the resulting hydrograph must be added to the ground-water hydrograph for the period covered.

The generally accepted method of reconstituting the hydrograph resulting from a group of storms is, as mentioned previously, to add, directly, the hydrographs resulting from the rainfall occurring in each unit of time, each one computed as if it were the run-off of an isolated, unit storm, using the distribution graph. The simplicity of this method is its strength. The hydrograph so developed, however, will follow an actual hydrograph only very imperfectly. One particular discrepancy that arises is that for a succession of storms of equal intensities, or a continuous rain, the method will frequently give a run-off rate exceeding the product of the rainfall rate and percentage of run-off. This is particularly true when the time to the peak of the unit hydrograph is very nearly the time of concentration. In such a case continuation of rainfall should not increase the discharge; but the method described adds to the peak the discharge of one day later on the falling limb, plus that of two days later, etc. Mr. Bernard recognized this effect, but attributed it to a flood wave.[8a] It is clear from the foregoing analysis that it is only the result of a flaw in the method.

The analysis of the characteristics of the basic hydrograph leads logically to a method of reconstituting hydrographs from rainfall. Underlying this method are two fundamental principles. The first is that the shape of the hydrograph resulting from a single storm is a function of the duration of the storm. The second is that the hydrograph resulting from a steady, continuous rain having superimposed on it a brief, heavy shower will be the sum of the hydrographs that would be produced by the two separately. This will be exactly true only on streams having a vertical stage-velocity relation; however, the similarity between hydrographs of storms of different magnitudes but of equal duration shows that little error is produced by accepting this assumption.

In records of the U. S Weather Bureau precipitation is recorded by days, and where unit hydrographs are the means of computing run-off, the records are used by days. In the proposed method, however, precipitation must be arranged "horizontally"; that is, where rainfall occurred on several successive days, it is divided into elements, each of which consists of a certain quantity of rain per day for the maximum number of days. This is more clearly illustrated in Fig. 6. Each of these elements, or "blocks," will produce a hydrograph of

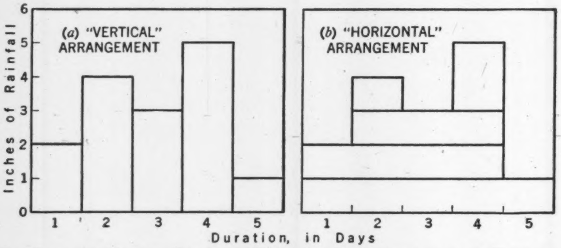

FIG. 6.—ARRANGEMENT OF RAINFALL DATA FOR RECONSTITUTION OF HYDROGRAPHS

different shape. The vertical scale of each hydrograph is proportional to the height of the corresponding block; analysis of the basic hydrograph provides the shape for each duration. These elements of the hydrograph may be added to each other directly until a time is reached when the rainfall rate, after having decreased, again increases, as on Day 4, Fig. 6. When this occurs the ordinate of the sum of the hydrographs resulting from preceding or lower blocks is carried as a constant through the duration of the additional block, and a rate of rainfall sufficient to maintain this flow is subtracted from the total rate during the period of the additional block. The hydrograph produced by the difference in rainfall is then computed and added to the other. At the end of this additional block of precipitation the underlying part of the hydrograph (all of the hydrograph other than that computed for the additional block of rain) reverts to the descending curve, which is the storage curve for the part of the rain that has ceased, plus the uniform flow from the part of the rain that continues. A sample computation is given in Appendix III.

[8a] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 189.

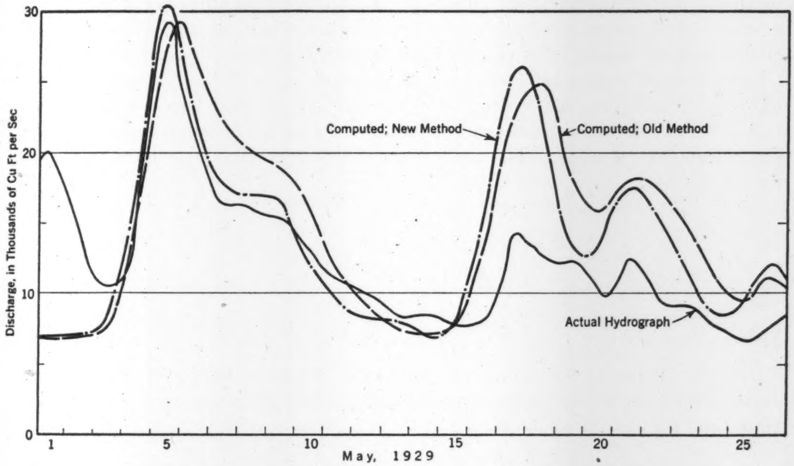

FIG. 7.—HYDROGRAPHS OF MERRIMAC RIVER, AT MANCHESTER, N. H.

The method described herein will produce a hydrograph which, in shape, will parallel an actual hydrograph, even reproducing minor fluctuations, whereas the hydrograph produced by the older method reproduces only the major undulations, and with a lesser degree of precision. Both methods rely very heavily on correct determination of percentage of run-off and groundwater flow. An example is offered by Fig. 7, which shows an actual hydrograph compared with hydrographs computed by the two methods described.

CONCLUSIONS

For studies in which time is short and great accuracy is not essential the use of unit hydrographs or distribution graphs, with their corresponding method of reconstituting a hydrograph, will be the most satisfactory method. In such case distribution curves similar to those shown in Fig. 5 will be found superior in accuracy to the unit hydrographs derived by the transposition method proposed by Mr. Sherman, and also much quicker, if hydrographs at a sufficient number of different locations are required to justify the labor of constructing the curves. Even for rather hasty studies the curves of annual percentage of run-off and ground-water flow will probably be found desirable. Where a high degree of accuracy is required, or for long-continued studies, the proposed methods will be found to be superior. Particularly in forecasting floods the greater degree of refinement should be of value. In such cases, the required curves and tables of daily run-off for various durations of precipitation, may be prepared in considerable detail. At any time, it will then be possible, very quickly, to compute the hydrograph that may be predicted to result from the rain to date. If future rain can be estimated for a day or two a more complete prediction can be made. The coefficients can be corrected from time to time as actual discharges become available.

APPENDIX I

Derivation of the Ratio of Successive Ordinates on a Storage Curve

As shown in the paper, the storage curve conforms to the general formula expressed by Equation (4); and the volume remaining in valley storage at any time is given by Equation (6). The volume flowing out during any time, t, is:

$$V_t = \int_0^t Q\,dt = \int_0^t e^{\alpha}\,dt = -\,C_2\left[e^{\alpha}\right]_0^t \ldots\ldots\ldots\ldots (9)$$

When $t = 0$, the exponent, α (see Equation (5)), becomes,

$$\frac{C_1 - t}{C_2} = \frac{C_1}{C_2} = \beta \ldots\ldots\ldots\ldots (10)$$

and, from Equation (10),

$$V_0 = C_2\,Q = C_2\,e^{\beta} \ldots\ldots\ldots\ldots (11)$$

When one-half the volume in storage has run-off, V_t is equal to V_s and equal to one-half the original volume; that is:

$$C_2\,e^{\beta} - C_2\,e^{\alpha} = 0.5\,C_2\,e^{\beta} \ldots\ldots\ldots\ldots (12)$$

or,

$$0.5\,C_2\,e^{\beta} = C_2\,e^{\alpha} = \frac{C_2\,e^{\beta}}{e^{\epsilon}} \ldots\ldots\ldots\ldots (13)$$

in which $\epsilon = \frac{t}{C_2}$. By elimination and transposition:

$$e^{\epsilon} = 2 \ldots\ldots\ldots\ldots (14a)$$

and

$$\epsilon = \frac{t}{C_2} = \log_e 2 \ldots\ldots\ldots\ldots (14b)$$

If the time interval required for one-half the volume to run off is designated as t_i, Equation (14*b*) becomes:

$$\frac{t_i}{C_2} = \log_e 2 \qquad (15a)$$

and,

$$t_i = C_2 \log_e 2 \qquad (15b)$$

As the ordinate, h, is equal to Q:

$$V_s = C_2 Q = C_2 h \qquad (16a)$$

$$C_2 = \frac{V_s}{h} \qquad (16b)$$

and,

$$t_i = \frac{V_s \log_e 2}{h} \qquad (16c)$$

Let $\frac{1}{t_i} = \frac{h}{V_s \log_2 2}$; then, the ratio of the two ordinates, one unit of time apart, is:

$$\lambda = 0.5^{\frac{1}{t_i}} \qquad (17)$$

that is,

$$\log_e \lambda = \frac{h \log_e 0.5}{V_s \log_e 2} = -\frac{h}{V_s} \qquad (18)$$

APPENDIX II

Sample Computation, Analysis of the Concentration Curve

Table 1 shows a sample computation form, in this case for the analysis of the concentration curve shown in Fig. 2. The time, y, and the dy-columns are self-explanatory. The values in Column (3) were computed from Equation (17). In the sub-storage curve for each time unit the first ordinate is dy; each ordinate is multiplied by the ratio shown to obtain the succeeding ordinate. In computing hydrographs for storms of short duration, the ordinates of each sub-curve are multiplied by the ratio of the duration of the storm to the mean time for the respective time unit (for Unit 3, Table 1, the mean time is 2.5; for Unit 7, it is 6.5, etc.), except where the time unit is prior to the cessation of the storm, in which case the full value is used. Thus, in a storm lasting four units, Curves (Units) 1 to 4 are used full value, Curve 5 is multiplied by $\frac{4}{4.5}$, Curve 6 by $\frac{4}{5.5}$, Curve 7 by $\frac{4}{6.5}$, etc. Run-off from each unit first appears at the time expressed by its number, and is at the maximum rate as long as the storm lasts, following the descending curve thereafter; or, if the storm has already ceased before its appearance, it follows immediately the curve, reduced proportionately as previously explained.

The same form shown in Table 1 is used in the synthesis of the concentration curve from hydrographs of storms of known duration, by the procedure described in the paper.

APPENDIX III

SAMPLE COMPUTATION OF RECONSTITUTED HYDROGRAPH

Appendix III offers an example of the computation of a hydrograph from rainfall data by means of the basic hydrograph. In this example, the rainfall shown in Fig. 6 will be used. It will be assumed that the drainage area for which the hydrograph is to be constructed has a space of 100 sq miles; a ground-water flow at this season of 3 cu ft per sec per sq mile; and a run-off factor at this season of 50 per cent. It will be further assumed that its basic hydrograph is known and has a time of concentration of three days, and that hydrographs for storms of one day and three days duration have been reduced to the distributions shown in Table 2.

TABLE 2.—DISTRIBUTION, IN PERCENTAGE OF DAILY RUN-OFF RATE

Description	(a) SUCCESSIVE DAYS; ONE-DAY STORM						(b) SUCCESSIVE DAYS; THREE-DAY STORM					
	1	2	3	4	5	6	1	2	3	4	5	6
Distribution	10	34	28	14	7	3.5	10	45	85	80	40	20

Stream flow on any later day will be one-half that on the preceding day. Flow on the fourth day of a longer storm will become 100% of the daily run-off rate, remaining at 100% for the duration of the storm, then going to 80%, 40%, etc., as in the case of the three-day storm (Table 2(*b*)).

A flow of 26.89 cu ft per sec for one day will be produced by 1 in. of run-off from 1 sq mile. The run-off, at 50% run-off factor, from 1 in. of rain per day on 100 sq miles is, therefore, 1 345 cu ft per sec. The rainfall shown on Fig. 6, being, on successive days, 2, 4, 3, 5 in., and 1 in., respectively, is the equivalent of: A five-day storm at 1 in. per day beginning on Day 1; a four-day storm at 1 in. per day beginning on Day 1; a three-day storm at 1 in. per day beginning on Day 2; a one-day storm of 1 in. beginning on Day 2; and a one-day storm of 2 in. beginning on Day 4.

TABLE 3.—COMPUTATION OF RECONSTRUCTED HYDROGRAPH: STANDARD PROCEDURE (UNITS ARE CUBIC FEET PER SECOND)

8	28	280	216	64	280
9	17	168	130	38	168
10	....	...	....	...	....

The computation is set up in Table 3. The run-off from the foregoing equivalent storms is shown in the columns headed "Daily Run-Off" (Columns (1) to (5)), each equivalent storm to one column, in the order given.

If an increase in rainfall should come when the hydrograph is falling, a special procedure is used. For example, assume a hydrograph to be falling after the cessation of a storm, with a ratio between successive ordinates equal to 0.60, as shown in Table 4 (Column (1)). A following storm, of intensity sufficient to produce a maximum run-off of 600 cu ft per sec, begins on Day 3, its hydrograph, if it had occurred alone, being as shown by Column (2). To combine the two, the ordinate on Day 2 is multiplied not by the ratio, 0.60, but by its square root, 0.77 (giving the ordinate at the beginning of Day 3 instead of at the middle of Day 3). This ordinate continues through the following storm, the ordinate that would have occurred on Day 3 now occurring on Day 7, the day following the end of the following storm, as shown in Column (3), Table (4). The increase in run-off under this hydrograph comes out of the run-off volume of the following storm, which must be reduced accordingly, so the modified hydrograph (Column (4), Table (4)) is in the ratio to that in Column (2) of $\frac{600 - 463}{600}$. The total run-off is the sum of Column (3) and Column (4), Table 4.

DISCUSSION

VICTOR H. COCHRANE,[9] M. AM. SOC. C. E. (by letter).—The graph which the author refers to as a "histogram" is very useful in the study of flood flows. That kind of histogram in which the abscissas express the time required for the water to flow to the point of measurement may be termed the time-area diagram. Its integral becomes the concentration curve, or ascending limb of the hydrograph, as stated by the author. It may also be employed in a simple manner to determine the ordinates of the descending limb of the hydrograph.

As an illustration, consider the simple case shown in Fig. 8. The watershed (Fig. 8(*a*)) is divided into six areas, or zones, such that the run-off therefrom, due to a rainfall of uniform intensity, arrives at the outlet in equal time intervals. The corresponding time-area diagram is shown in Fig. 8(*b*), and the resulting hydrograph in Fig. 8(*c*). The ordinates for the concentration curve are computed by summing the zone areas, as shown in Table 5. If the velocities during the falling stage were the same as during the concentration period, the ordinates of the descending limb of the hydrograph would be obtained directly by deducting from the peak flow the various zone contributions in succession, as in Table 5. The resulting curve is shown in the broken line, Fig. 8(*c*). This curve, plotted downward with reference to the horizontal line representing the peak flow, is the same as the concentration curve. It will be seen that if the ascending limb of the hydrograph rises slowly in the early stages, due to the narrowness of the water-shed or the flatness of the slopes near the outlet, the hydrograph tends to fall slowly after the peak, and *vice versa*.

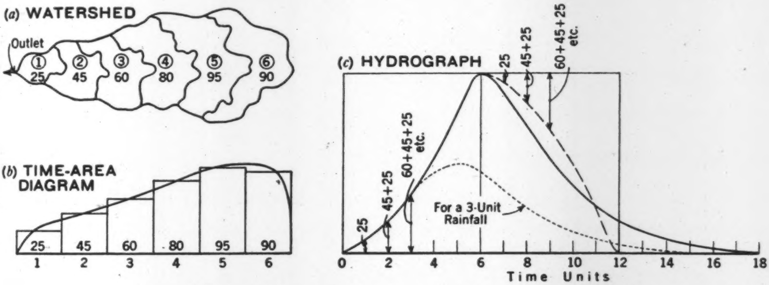

FIG. 8.—WATER-SHED, TIME-AREA DIAGRAM, AND HYDROGRAPH

The base of the falling limb of the hydrograph must exceed that of the rising limb. That this is true will be seen upon consideration of the flow from the zone farthest up stream. The initial run-off from this zone rides the crest of the flood, as it were, during the concentration period, thus traveling to the outlet at the maximum velocity. The final contribution flows at, or a little above, the base stage, with a relatively low velocity. The base of the hydrograph for falling stages is the time required for the water to travel from the most remote zone to the outlet at the ordinary or low-water stage of the stream. For practical purposes, a somewhat shorter time may be used, as the flow at final stages is relatively small. The base flow definitely limits the length of the flood period. Where the author states (following Equation (3)) that "the length of base is actually infinite," he is referring no doubt to the mathematical characteristics of his formula.

11	Corresponding abscissa; unit times*	6.50	7.56	8.80	10.42	12.71	16.03

* Base of hydrograph is 18 time units.

After the peak flow is reached, the velocity, which varies approximately as the square root of the hydraulic radius, decreases quite slowly at first; then much more rapidly during the last stages of the flood. The rate of change in velocity with respect to time can be determined approximately from the characteristics of the stream channel. As the time period corresponding to a given element of flow is lengthened, the discharge in unit time is decreased in inverse ratio. In Table 5 the increase in length-of-flow periods is assumed to vary as the cube of the number of units of flow (six in this case), and the base of the descending limb is twice that of the ascending limb. The resulting curve is shown in Fig. 8(*c*).

For a rainfall extending over a shorter period than that producing the maximum flow, the summations and adjustments are made in a similar manner. In Table 5 the summations would include as many terms in each horizontal line as there are periods of precipitation. The dotted line in Fig. 8(*c*) shows the hydrograph for a rainfall extending over three time units.

The author's unqualified assertion that there is a sharp break in the basic hydrograph is therefore open to question. Such a break might be observed in the case of a stream with a wide fan-shaped area at the down-stream end and a long narrow valley farther up stream. In a water-shed of this type the maximum flow might come from a rainfall covering only the lower part of the drainage area, the concentration period being shorter, and the intensity of precipitation greater, than for the full area. The author's logarithmic formula gives ordinates too small for the upper part of the curve and too large for the lower part. In Fig. 9, Curve A shows the falling limb constructed by the method just described, assuming a base length double that of the concentration curve, and Curve B is derived from Table 1.

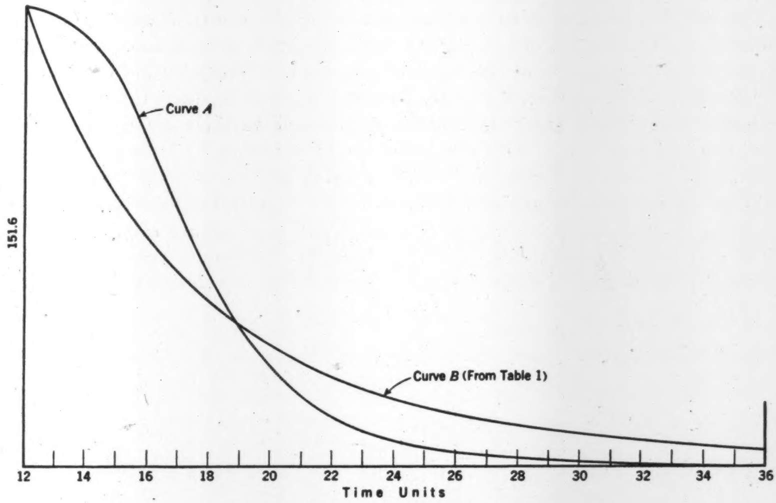

FIG. 9.—COMPARATIVE HYDROGRAPHS

For a given uniform intensity of precipitation and a constant run-off rate, the peak flow per unit of area is the same regardless of the size or shape of the water-shed. The pattern of the drainage area becomes a factor in case the rainfall is of variable intensity with respect to time or area. Inasmuch as the average intensity diminishes rapidly with increase of time, the time of concentration (the length of stream divided by the average velocity) is a much more reliable indicator of maximum discharge than either area or length of water-shed. The writer has heretofore proposed formulas[10] for maximum discharge from small water-sheds, as follows:

$$q = c\,I\,(A + B) \qquad (19)$$

in which, for $T = 1$ hr or less,

$$A = 645\,\frac{6 + I}{6\,T + I} \qquad (20a)$$

or, for T greater than 1 hr,

$$A = \frac{645}{T^{0.75}} \qquad (20b)$$

and

$$B = 100\,(z - 1)\,\frac{6\sqrt{T} - T}{0.4\,I + T} \qquad (21)$$

In Equations (19), (20), and (21): q = flood discharge in cu ft per sec per sq mile of drainage area; c = the ratio of run-off to rainfall; I = average intensity of maximum precipitation for the aggregate period of 1 hr during a given storm; T = time of concentration in hours; and z = ratio of maximum to average area of divisions of the time-area diagram (or, roughly, the ratio of maximum width of water-shed to the mean width).

---

[10] *Engineering News-Record*, November 25, 1937, p. 864.

It will be seen that these expressions are designed to improve the rational formula in two respects: The intensity of precipitation is made to vary with the time of concentration, and the effect of non-uniform precipitation is included. In Equation (19) the term A expresses the flow due to a uniform rate of rainfall, whereas the term B gives the additional flow due to the most extreme non-uniform precipitation. With the exception of the run-off coefficient, c, these equations contain no terms with widely varying and uncertain values, such as appear in many other run-off formulas. The time-intensity relationship in Equation (20*a*) has been shown[11] to agree well with actual rainfall records. The empirical expression for B in Equation (21) represents values computed from typical time-area diagrams, assuming that the maximum run-off occurs when the contribution from the maximum area, due to the most intense precipitation, arrives at the outlet.

TABLE 6.—VALUES OF q FOR: $I = 3.0$; $c = 0.5$; AND $z = 1.5$

Description	VALUES CORRESPONDING TO TIME OF CONCENTRATION, T, IN HOURS						
	0	0.25	0.50	1	6	12	24
Average intensity, I, in inches	9	6	4.5	3	0.78	0.465	0.276
Substitution Factors:							
A (Equations (20))	1 935	1 290	967	645	168	100	59.5
B (Equation (21))	0	95	110	113	61	33	10.5
q (Equation (19))	2 900	2 080	1 615	1 137	344	200	105

These formulas may be useful in estimating peak flows for water-sheds of different sizes. They cover the entire range of possible values. The four variables used, c, I, T, and z, may be evaluated for any particular case by the application of appropriate methods or pertinent data.

Values of q are shown in Table 6 for $I = 3.0$, $c = 0.5$, and $z = 1.5$. It will be noted that q diminishes very rapidly as the time of concentration increases.

In Equation (20*b*), the exponent of T $(= 0.75)$ is an average value, convenient for use with the slide-rule. Other values may be used to suit the rainfall characteristics. The average intensity per hour, i, for a 24-hr period, may be substituted for the term, I, according to the relation, $I = 10.9\, i$.

The foregoing formulas should be of use in transposing basic hydrographs, or in checking results obtained by other methods. They afford a clear picture of the effect of variations in the principal factors involved in flood discharge.

BERTRAM S. BARNES,[12] ASSOC. M. AM. SOC. C. E. (by letter).—The new and original attack upon the problem of constructing discharge hydrographs of run-off from observed rainfall, as presented by Mr. Meyer, will arouse considerable interest and will give a new impetus to research in this field. The author has admirably reconciled the apparently opposite viewpoints of the advocates of the unit hydrograph and of the depletion curve.

[11] *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 369.

[12] Hydrologic Supervisor, Upper Mississippi Region, U. S. Weather Bureau, Iowa City, Iowa.

The assumption that run-off is proportional to rainfall will give much more satisfactory results in hilly country, where a relatively large part of the rainfall enters the stream channels at once, than it will in a flat country where most of the rain goes into the ground. Under the latter conditions, fluctuations in the momentary intensity of rainfall may have a pronounced effect upon the amount of run-off. The run-off factor is one of those devices used for lack of anything better. Its use is made necessary in most cases by the imperfect state of the present-day knowledge of the relation between rainfall and run-off, and because of the absence of sufficient basic data. Hydrologists should not lose sight of the fact that the idea of a run-off factor is a poor concept at best, and that its use is likely to produce very unsatisfactory results wherever the infiltration is large and rainfall varies greatly in momentary intensity. It is unquestionably true that the average monthly or weekly value of the run-off factor rises and falls with the ground-water level. In some cases it even appears for a time to maintain a fixed relation to the rate of ground-water flow, although this must be considered pure coincidence. In the Mississippi Valley the variation of the run-off factor from day to day is frequently so great that an average value, or one predicted from the calendar, has been found to be of little use when the unit hydrograph method was employed. There is urgent need for the development of better methods of predicting the quantity of run-off from a given storm.

Another fact frequently overlooked in present-day studies is that the time of concentration, as it is usually defined, is not necessarily identical with the elapsed time from the occurrence of rainfall to the peak of the run-off. In basins of irregular shape there will almost always be flow from certain tributaries which will still be increasing after the peak of discharge from the basin has passed.

The assumption that, after the storm water has ceased to flow from the surface of the ground, the streams have no source of replenishment other than ground-water flow is one that should be given more critical study, or at least a definite interpretation. Ordinarily, ground-water flow is thought of as the discharge from water held in storage at, or below, the ground-water table. Two or three weeks may sometimes elapse between a rainstorm and the increase in ground-water flow which results from it. Many streams in the Mississippi Valley receive storm water from two immediate sources: (1) The drainage from the ground surface into the stream channels during and immediately after the rain; and (2) what appears to be a lateral movement of percolating water in the upper soil layers, entering the stream channels in the form of seepage, and reaching its maximum flow about 2 days after the peak of storm flow. The latter phenomenon was noted by the writer when making some studies of Zumbro River, in Minnesota, in 1936, and was given the name "secondary base flow." The same, or something quite similar, was observed by Mr. C. R. Hursh[13] and called by him "subsurface storm flow."

---

[13] *Transactions*, American Geophysical Union, 1936, p. 302.

Separation of the storm run-off into surface flow and secondary base flow has been made for a number of streams in the Mississippi Valley. In order to obtain satisfactory results it was necessary to determine the discharge at intervals of 6 hr or less, rather than to use daily averages. It has been found that the recession of each of these components of flow can be plotted as a straight line on semi-logarithmic paper. The formula used in the office of the writer is

$$Q_t = Q_0 K^t \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

in which Q_0 is the discharge at any instant; Q_t is the discharge t days later; and K is known as the "daily depletion factor," its value for secondary base flow being much higher than for surface flow.

Equation (22) can be derived from that proposed by W. W. Horner, M. Am. Soc. C. E., and F. L. Flynt, Assoc. M. Am. Soc. C. E.[14] It should be noted that flow from only one source (surface) was used in developing the Horner and Flynt formula.

In the case of the Iowa River at Marshalltown, Iowa, for a concrete example, it has been found that the secondary base flow becomes appreciable in about 12 hr after the peak of storm discharge has passed and reaches a maximum in from 60 to 65 hr after the peak of storm discharge. At that time it may become as much as four times the surface discharge, or 80% of the total storm discharge. The peak of the hydrograph of secondary base flow has a fairly flat top of about 40-hr duration, compared with about 10 hr for the peak of surface flow, and a depletion factor, K, equal to 0.69, as compared with 0.33 for surface flow. The ratio of the total secondary base run-off to the total storm run-off varies quite widely. For gentle rains the peak discharge of secondary base flow at Marshalltown is about 20% to 25% of the peak discharge of surface flow. For rains of high momentary intensity the ratio may be considerably smaller.

Studies, made in the writer's office, of the flow of the Iowa River at Marshalltown, and that of certain other streams, show that the recession of the ground-water flow can be expressed by Equation (22) during periods when no recharge is taking place (the value of K at Marshalltown for ground-water flow is 0.98). It follows, therefore, that for each of the components of flow the quantity of water remaining in live storage at any time during a true recession is directly proportional to the discharge of the component. This reasoning cannot be applied strictly to any flow that includes discharge from more than one of the three sources previously described.

LEROY K. SHERMAN,[15] M. AM. SOC. C. E. (by letter).—Since the introduction of the unit graph method,[2] several improvements have resulted, and a keener appreciation of the value of interpreting the hydrograph has developed. The author has presented a useful review of run-off characteristics and has outlined certain original procedures. This discussion will be confined first to brief comments on the fundamental principles and will be followed by a critical analysis of some of the author's conclusions and suggested procedure.

---

[14] *Transactions*, Am. Soc. C. E., 1936, Equation (1), p. 151.

[15] Cons. Engr., Chicago, Ill.

Mathematical derivation of the rising and falling stages of the hydrograph has been studied carefully by several hydrologists. In addition to those referred to by the author, the work of Franklin F. Snyder,[16] Jun. Am. Soc. C. E., published in 1938, should be noted.

Synthetic hydrographs serve a useful purpose. The test of such work is their correlation with observed graphs. When reliable observed hydrographs are available, they should be used in preference to any other basis. Nature integrates all of the factors with no oversights or assumptions.

Transposition of hydrographs may also be useful in the absence of a record. The criticism of the writer's paper on transposition (see heading "Transposition of Hydrographs") is well taken. Smaller areas generally have the steeper slopes. The use of diagrams of distribution percentages on successive days, as illustrated by Fig. 4, should prove useful in many cases.

The time of concentration has been used in many ways. The writer concurs with the definition (see "Synopsis") that concentration, under a continuous rain of uniform intensity, is "the length of time until the run-off becomes constant." The velocity of the stream generally increases with the stage, but it is fairly constant at higher stages. For this reason, best results with the unit graph method are obtained with unit distribution percentages derived from the higher storm intensities. The time of concentration for a given basin, therefore, will be relatively long for the lighter rains. In the case of overland flow, the time of concentration may be materially affected by the original moisture content of soil and vegetation. Variations of from 22 to 50 min have been observed on the same sod covered plots.

Fig. 5 is a constructive suggestion in estimating base flow. The author states (see paragraph before "Conclusions"): "Both methods rely very heavily on correct determination of percentage of run-off and ground-water flow." This truth is worthy of amplification. Net rainfall is not primarily a percentage of rainfall. It is rainfall minus infiltration, after surface run-off begins. Wherever automatic-recording data of rainfall and run-off are available, or wherever the soil infiltration capacity is known, run-off can be estimated accurately by the unit graph or by some other methods (see Table 7). When only daily quantities of precipitation are given, it is impossible to know whether this rain fell in 2 hr or 10 hr. In this case, the estimate will be more or less approximate and estimated percentages of run-off will suffice.

In Fig. 3, the uniform rate of net rainfall persisted for five units of time and ceased at the time of concentration. The tail of this graph ended six time units after the concentration period, or Time 11. If the rain ceased at the end of Time 2, the figure shows (at the bottom of the hatched area) the termination of run-off at the same point—Time 11. This violates two observed facts in nature: (1) For a uniform rate of rainfall, the time base of the hydrograph for a short rain is less than the time base for a longer rainfall; and (2) for any duration of rainfall the area (volume) of the tail of the hydrograph is equal to the area (volume) of net rainfall, up to said duration, above the hydrograph. This accords with the storage equation.

---

[16] "Synthetic Unit Graphs," by Franklin F. Snyder, *Transactions*, Am. Geophysical Union, 1938, Part I.

The author criticizes the unit graph method, particularly with reference to applications extending beyond the time of concentration. He states that the method will follow an actual hydrograph very imperfectly, sometimes giving results in excess of true run-off rates. He proposes another method.

TABLE 7.—ALTERNATE METHOD OF ANALYZING A CONCENTRATION CURVE

Time (ten-minute units)	Rainfall, in inches per hour	Infiltration, in inches per hour	Net rainfall, in inches per hour	Distribution (percentages)	SUCCESSIVE ORDINATES								
					10	20	30	40	50	60	Total to 60	65	Total to 65
10	1.73	0.18	1.55	35.8	0.55	....	....	....	....	....	0.55	....	0.55
20	1.73	0.18	1.55	43.6	0.68	0.55	....	....	....	....	1.23	....	1.23
30	1.73	0.15	1.58	12.0	0.19	0.68	0.57	....	....	....	1.44	....	1.44
40	1.73	0.15	1.58	5.0	0.08	0.19	0.69	0.57	....	....	1.53	....	1.53
50	1.73	0.13	1.60	3.6	0.05	0.08	0.19	0.69	0.58	....	1.59	....	1.59
60	1.73	0.13	1.60	....	....	0.05	0.08	0.19	0.70	0.58	1.60	0.29	1.60
65	Stop	0.13	1.60	....	....	....	0.05	0.08	0.19	0.70	1.02	0.35	1.38
....	....	....	....	....	....	....	....	0.05	0.08	0.19	0.32	0.10	0.58
....	....	....	....	....	....	....	....	....	0.05	0.08	0.13	0.04	0.23
....	....	....	....	....	....	....	....	....	....	0.05	0.05	0.02	0.13
Totals	....	....	10.26	100.0	1.55	1.55	1.58	1.58	1.60	1.60	9.46	0.80	10.26

The writer has not observed such discrepancies unless the unit graph method was misapplied or unless the data for a unit or distribution graph were inadequate. The writer presented a hypothetical concentration-time graph in his original paper.[2] He had not, however, tested the method against an actual hydrograph extended beyond the time of concentration. As a check, therefore, he has computed a hydrograph of run-off due to an actual rain of 1.73 in.

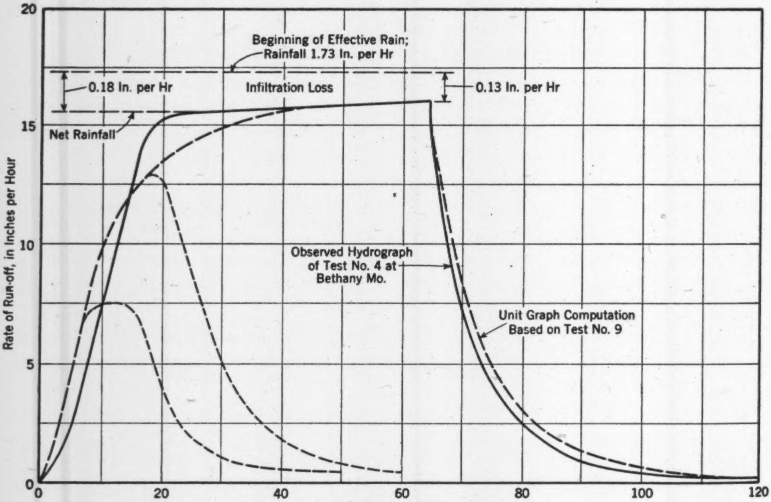

FIG. 10.—COMPARISON OF COMPUTED WITH OBSERVED HYDROGRAPH

per hr for 65 min, with a known run-off of 89 per cent. The computations are shown in Table 7. The computed hydrograph is shown in dotted line on Fig. 10. The observed hydrograph, shown solid, is one of a series of tests made in the Fall of 1937 at the Soil Conservation Experiment Station at Bethany, Mo., by Messrs. C. M. Woodruff, Dwight D. Smith and Darnell M. Whitt. A rainfall simulator was used on a plot 7 ft wide and 73.6 ft long. The slope was 7.19% covered with blue-grass sod.

The writer derived a 10-min distribution from an observed hydrograph known as Test No. 4. He applied this distribution to the rainfall data of an entirely different "storm" designated as Test No. 9.

The result speaks for itself and the writer offers no apologies for the unit graph method as a practical working tool.

The observed infiltration rates, as given for Test No. 9, were used. Almost identical results would have accrued had the writer used the average infiltration capacity of 0.158 in. per hr based upon the average of 15 tests made at Bethany.

Apparently Fig. 7 is inconclusive. One peak is checked very well by both methods. The other peak is checked very poorly by both methods. The writer suggests that if an infiltration capacity had been used, instead of a percentage of run-off, both results would have checked.

In Appendix III, Table 2, the percentage distributions for a hypothetical one-day storm and a three-day storm are given, together with the statement that three days constitute the time of concentration. The writer cannot reconcile these statements. Both conditions cannot be assumed. Each is a function of the one-day distribution. It is to be regretted that the comparison, such as Tables 3 and 4, was not checked against an observed hydrograph.

The author may have developed a desirable principle that would effect an improvement over the unit graph method, but, in the writer's opinion, this has not been demonstrated in the paper.

RICHMOND T. ZOCH,[17] ESQ. (by letter).—An interesting application of certain theories of rainfall, run-off, and stream flow is contained in this paper, and it is gratifying to find many of the assumptions, upon which Mr. Meyer's paper is based, explicitly stated. In the past, many of the writers dealing with this subject have not stated the assumptions involved nearly as explicitly. It is gratifying also to find the concept of the histogram of the drainage area mentioned.

Mr. Meyer's treatment of the depletion curve (which he calls the storage curve) is theoretically sound, practically convenient and commendable, with the exception that, strictly speaking, the depletion curve begins at a time equal to the concentration time plus the duration of the rain. His treatment of the concentration curve (a section of the hydrograph which he has also named most appropriately) is also theoretically sound and practically convenient; but only so in the section of the hydrograph which comes before the end of the rain, or the concentration time, depending on which of these two times comes first.

---

[17] Meteorologist in Chg. of Library, U. S. Dept. of Agriculture, Weather Bureau, Washington, D. C.

Mr. Meyer's presentation is usually clear, but he makes a number of statements which do not seem to be entirely correct. Most of these are in the paragraphs under the heading, "Analysis of the Hydrograph," and it is believed well to point out in detail the statements in which the writer's views differ from Mr. Meyer's. For example, he states, "* * * after a short time lag the run-off will be approximately proportional to the rainfall," and further, "It is assumed permissible to treat the run-off as a constant percentage of a uniform rain." These statements require much explanation in discussing them. First, it is necessary to distinguish between run-off and rainfall on the one hand, and the rate of run-off and rate of rainfall on the other. The first two are measured in inches and indicate depths of water which have run-off or fallen, respectively, up to time *t*, whereas the other two are measured in inches per hour and are, respectively, the depth of water running off, or falling, per unit time at a given instant of time.

Again, as regards run-off and rate of run-off, it is necessary to distinguish carefully between true surface run-off and underground (internal) drainage. When the soil is not saturated, there is always some infiltration and internal drainage, but the rate of infiltration may exceed the rate of internal drainage. As soon as the soil is completely saturated, there is still infiltration because there is also internal drainage; but the two are equal, and with a uniform continuous rate of rainfall the rate of internal drainage is a constant percentage of the rate of rainfall. Furthermore, after a steady state has been reached (which time may occur simultaneously with, or some time after, but never before, the time of complete saturation of the soil), the rate of the surface run-off is a constant percentage of the rate of rainfall. It is this condition which Mr. Meyer probably had in mind when he made the second statement quoted.

Consider next the capacity of the soil to retain water. The soil may retain water by internal absorption, or it may retain water as surface pondage. In the theoretical treatment of rainfall, run-off, and discharge, it is always possible to distinguish between the internal capacity of the soil and its external (surface) capacity. However, and naturally, the equations involved are more simple if this distinction is not made. Again, from the practical point of view the distinction is certainly not always necessary, because nearly all the internal drainage subsequently appears as discharge. In a stream large enough properly to be spoken of as a river, only the internal drainage in the immediate vicinity (broadly speaking) of the gage will not appear as discharge at the gage. Go to the soil a little distance away from the gage, as well as all the soil still farther up stream, and all the internal drainage, just the same as all the true surface run-off, will appear as discharge at the gage. For this practical reason, as well as the theoretical reason of simplicity, in the following remarks run-off and rate of run-off are considered in the broad sense of the combined surface run-off (or rate of run-off) and internal drainage (or rate of internal drainage).

Consider now the foregoing statements of Mr. Meyer from the point of view of rate of rainfall and rate of run-off. Whether the rate of rainfall is uniform or not, the rate of run-off is never even approximately proportional to the rate of rainfall. After a sufficiently long time (theoretically an infinitely long time—as Mr. Meyer himself states on a later page in another connection—but practically, after the lapse of a number of hours, depending on the nature and condition of the soil), with a uniform continuous rate of rainfall, the rate of run-off must equal the rate of rainfall. This sufficiently long time, of course, must be long enough for the soil to become completely saturated—or water-logged would probably be a better term—and the rate of infiltration is exactly equal to the rate of internal drainage. At no moment during this period of approach to the time when the rate of run-off will be exactly equal to the rate of rainfall, however, is the rate of run-off approximately proportional to the rate of rainfall. The rate of run-off is proportional, however, to the water remaining with the soil. In many cases, the rate of run-off will be a constant percentage of the water remaining with the soil, although in some cases undoubtedly it is a function of the amount remaining with the soil rather than a constant percentage. The percentage of the rate of rainfall running off at any instant of time steadily increases from the beginning of the rain until a time is reached when the rate of run-off is exactly equal to the rate of rainfall.

The steady state of run-off is that state at which the rate of run-off exactly equals the rate of rainfall. There is also a steady state of discharge, but it always comes some time after the steady state of run-off.

From the foregoing considerations, which are perfectly straightforward and simple, it is possible to set up a differential equation and from it to find the exact mathematical expression which represents the rate of run-off as a function of the rate of rainfall for any given time. This has actually been done by the writer in the paper to which Mr. Meyer refers,[8] and it forms the basis of later papers following it, to which Mr. Meyer does not refer.[18, 19] The differential equation[8] gives rise to an equation which contains the exponential function. This equation probably represents what actually takes place in Nature with remarkable exactness as the time of the steady state is approached; but in the initial range (that is, immediately after the beginning of the rain) it may be only a rough approximation to what occurs in Nature. For this reason the idea of treating the rate of run-off as a function rather than as a constant percentage of the water remaining with the soil has been recognized and, to a certain extent, treated.[19]

Consider next the statements by Mr. Meyer from the point of view of run-off and rainfall. The rainfall that has fallen up to time t is represented by $r\,t$, in which r is the rate of rainfall and t is the time, whereas the run-off which has disappeared up to time t is represented by $(r\,t - r\,c)$, in which c is the capacity of the soil. Clearly, one cannot say that, as the rain continues at a uniform rate (that is, as t increases), the run-off that has disappeared at time t is a constant percentage of the rainfall that has fallen up to time t.

The statement, "In actual cases the hydrograph is not expected to vary greatly in shape from one produced by rain of uniform distribution," is one on which the writer is not prepared to comment, but it certainly seems that

---

[18] *Monthly Weather Review*, Vol. 64, April, 1936; and, Vol. 65, April, 1937.

[19] *Transactions*, Am. Geophysical Union, 18th Annual Meeting, 1937, pp. 425–426.

this statement is worthy of further investigation before being accepted unconditionally.

There is confusion in the paper between the terms "volume of rate of run-off" and "discharge." The latter is the water flowing in a stream and takes account of the time between the moment the water falls to the ground as rain and the instant it reaches the point on the stream at which the discharge is being measured; and this time is a variable quantity increasing with increasing distance from the gage. The volume of rate of run-off is the water disappearing from the soil at any moment of time into the numerous steam channels of a drainage area. Both of these terms are expressed in cubic feet per second, and this may partly account for the confusion between the two. In the statement, "Assuming a uniform, continuous rain, the [discharge] passing any point on the stream will increase as water from more distant parts of the drainage area comes to the point of measurement, * * *," the writer has substituted the word "discharge" for Mr. Meyer's word, "run-off." The discharge does not reach a maximum at, nor does it become constant after, the time of concentration. For a drainage area, the width of which never decreases with increasing distance from the gage, this maximum cannot precede the concentration time; but even in drainage areas of this class the discharge does not become constant after this time. For drainage areas, the width of which decreases with increasing distance from the gage, the maximum discharge may precede the time of concentration. The duration of the rainfall itself has an important bearing on the time of the maximum discharge. The duration may be quite short, especially in thunderstorm types of rain, whereas during the winter season the duration may be very long, and the maximum discharge for any uniform continuous rate of rainfall can never precede the time when the rain stops. Hence, if the duration exceeds the concentration time there will be no distinction in the time of occurrence of the maximum discharge arising from different shapes of drainage areas.

Quoting Mr. Meyer: "As the streams then have no source of replenishment other than ground-water flow, which has been eliminated from consideration, all flow thereafter must come from depletion of the water in channel or valley storage." In considering this statement, in place of ground-water flow, which, as Mr. Meyer states, can be eliminated from consideration, eliminate from consideration the stream flow at the time the rain began. By doing this, only the flow due to the rain under discussion is considered. Just the same, much of the stream flow resulting from a given rain is due to water which at some time during the course of its journey from the spot where it fell as rain to the gage on the river was under the surface of the soil. This is true although the soil may have been completely saturated at the beginning of the rain, because even in this case of saturation there is infiltration into the soil, and the rate of infiltration in such a case is equal to the rate of internal drainage. Thus, after a time equal to the sum of the concentration time, plus the duration of the rain, flow results not only from depletion of the water in the channel storage, but also from depletion of the water within the soil which entered the soil during the current rain under consideration.

In the sentence beginning at Line 5 below Equation (3), the word "discharge" occurs four times. This statement is entirely correct if in each case the term "discharge" is replaced by "volume of rate of run-off," or also by "rate of run-off," but, applied to discharge it is never strictly correct from the theoretical point of view, and seldom approximately correct even from the practical point of view.

The statement, "the increase in ordinate of the hydrograph per unit of time is proportional to the additional area, water from which first reached the point of measurement during that unit of time," is only partly correct. Throughout the period of time when the discharge is represented by the curve which Mr. Meyer very fittingly calls the "concentration curve," the discharge is increasing for two different reasons: First, the soil in the drainage area is approaching the limit of its capacity for water and hence a greater and greater portion of the rain falling upon the drainage area is flowing off as free water; and secondly, the area that contributes to the discharge is increasing. After the concentration time, the entire drainage area above the gage is contributing to the discharge, and then the discharge continues to increase, but from the first cause only.

"This break has actually been found on continuous gage records (see Fig. 1), although storms of sufficient duration to produce actual basic hydrographs on large drainage areas are * * *" implies that Mr. Meyer believes that for a rain, the duration of which equals the concentration time, a sharp break occurs in the hydrograph. It is quite true that hydrographs are encountered with such sharp breaks, but these breaks are never due to the concentration time equaling the duration of the rain. They may be caused by moving showers of rain which must move down stream rather than up stream, but a uniform continuous rain will never produce a hydrograph with a sharp break in it, except in the very special case of a heavy rain with a very short duration (practically, the duration of the rain would have to be less than one hour).

Mr. Meyer regards the hydrograph as consisting of only two parts, the first of which he calls by the very descriptive title, the "concentration curve." Generally, for constant rates of rainfall, the hydrograph consists of four distinct parts, which are not in the same order in all cases. Suppose, first, that the duration of the rain is greater than the concentration time. Then the four parts of the hydrograph are as follows: (1) The concentration curve from the beginning of the rain until the concentration time; (2) the saturation curve when the area contributing to the discharge is constant, after the concentration time; (3) the period after the rain stops; and (4) the depletion curve.

Part (1).—During this interval the area contributing to the discharge at the gage is steadily increasing.

Part (2).—After the concentration time, the area contributing to the discharge does not increase, but remains constant; the discharge increases, however, approaching a steady state at which the discharge is equal to the volume of rate of rainfall falling upon the drainage area. During this interval (which, theoretically, may last an infinitely long time, but practically, lasts as long as the rain continues at a constant rate) the hydrograph is represented by the saturation curve, which is asymptotic to the straight line that would represent the discharge at a steady state.

Part (3).—After the rain stops, the discharge is no longer represented by the saturation curve. If a steady state has been reached (practically, for a drainage area large enough properly to be called a river basin, such a steady state of discharge is almost never reached) the discharge decreases immediately. If a steady state has not been reached, the discharge increases after the rain stops until the time of the crest. Here the hydrograph is represented by the transition curve which contains the crest of the flood. The transition curve extends from the end of the rain until a time equal to the duration of the rain, plus the concentration time.

Part (4).—Finally, there is a depletion curve, which extends from a time equal to the duration of the rain, plus the concentration time until, theoretically, an infinite time later, but practically until the beginning of the next rain.

If the duration of the rain is less than the concentration time, obviously, there is no saturation curve. There are still four sections to the hydrograph and a distinction is also caused from the shape of the drainage area. If the drainage area is fan-shaped—that is, if the width of the drainage area increases with increasing distance from the gage—the maximum discharge must follow the concentration time regardless of how short the duration of the rain may be. In that case there are: (1) A concentration curve from the beginning of the rain until the rain stops; (2) a curve of slow rise from the time the rain stops until the concentration time; (3) a transition curve from the concentration time until a time equal to the duration of the rain, plus the concentration time; and (4) a depletion curve.

If the drainage area is such that its width decreases with increasing distance from the gage, the crest may occur before the concentration time. Then there are: (1) A concentration curve from the beginning of the rain until the rain stops; (2) a transition curve from the time the rain stops until the concentration time; (3) a curve of slow fall from the concentration time until a time equal to the duration of the rain, plus the concentration time; and (4) a depletion curve.

Thus, generally, there are four parts to the hydrograph. If the rain is infinitely short (practically, less than one hour), the hydrograph consists of only two parts: Part (1), a curve of rise, and Part (2), a depletion curve. If the duration of the rain is exactly equal to the concentration time, the hydrograph consists of three parts: Part (1), a concentration curve; Part (2), a transition curve; and Part (3), a depletion curve—the saturation curve being completely absent.

It is for these reasons that the writer believes Mr. Meyer's treatment to be fully the equal of any that has been proposed heretofore for very short rains; but he does not believe it proper to consider Mr. Meyer's "basic hydrograph" as having only two parts. His "basic hydrograph" is naturally divided into three sections and cannot be closely represented by a graph of only two sections.

One point on which Mr. Meyer does not comment (except in the statement which has been quoted about the discharge reaching a maximum and becoming constant at the concentration time) is the determination of the time when the maximum discharge occurs. It has been shown[8] that for a rectangular drainage area, using essentially the same assumptions that Mr. Meyer uses, the time of the maximum discharge is expressed by the function

$$t_c = c \log \left(e^{\frac{L}{cv}} + e^{\frac{t_0}{c}} - 1\right) \dots\dots\dots\dots\dots\dots (23)$$

In this function t_c is the time of the crest or maximum discharge, measured from the beginning of the rain; t_0 is the duration of the rainfall; L is the distance from the gage to the source of the stream; and, v is the velocity of the water. Thus, $\frac{L}{v}$ equals the concentration time, and it should be observed that this function is symmetrical in $\frac{L}{v}$ and t_0; and, c is the capacity of the soil to absorb water either internally or as surface pondage. Naturally, with a differently shaped drainage area or with different assumptions of velocity, soil capacity, rates of rainfall and evaporation, this function requires modification. As stated previously, it is possible to separate c into that part which absorbs water internally and the part which is due to surface pondage; but for simplicity they are combined here. Naturally, when they are separated, the function which represents the time of the crest is a more complicated one, and a simple function is here taken merely to illustrate that, even when these capacities are combined, they influence the time of the crest appreciably, and when they are separated the influence upon the time of the crest is still more marked. This function shows that the time of the crest for this particular shape of a drainage area cannot occur before the concentration time, and neither can it occur before the ending of the rain. The capacity of the soil to retain water is measured in hours, and when the capacity c is said to equal a certain number of hours (say, 10 hr), one means that at the end of 10 hr from the beginning of the rain, the rate of run-off from the soil will be $\left(1 - \frac{1}{e}\right)$ times the rate of rainfall that is falling upon the ground. Thus, the capacity of the soil is a time constant, and is the time at which the rate of run-off reaches 0.632 of its final value. Clearly, this method of expressing the capacity of the soil is simple and convenient. For example, the capacity of the soil may be low. That is, the rate of infiltration may be low, or the soil may be fairly well saturated with water at the beginning of the rain; or, even if no water is on the soil at the beginning of the rain, it may be steep, and hence the surface pondage factor would be low. All of these conditions make the capacity of the soil low, and they also mean that the rate of run-off will approach the rate of rainfall more rapidly than it would if the capacity were high. By measuring the capacity of the soil in time, then, one measures the rapidity with which the rate of run-off approaches the rate of rainfall.

The time of the crest, as represented by Equation (23), is not greatly influenced by the capacity of the soil when the ratio of the duration of the rain to the concentration time is very large or very small (depending, of course, on which is the larger) but, when the duration of the rain and the concentration time are nearly equal, as Mr. Meyer chose them for his "basic hydrograph," the time of the crest is quite sensitive to the varying capacity of the soil. Table 8 (Columns (2) and (3)) illustrates this fact, where the concentration time and the duration of rain are given the same value of 50 hr, but the capacity has the different values shown. The times of the crest given in Table 8, Column (2), have been computed by means of Equation (23).

Naturally, the change in the time of the crest influences the shape of the hydrograph, and this illustrates one of the fundamental and outstanding defects of the concept of the unit hydrograph itself. The unit hydrograph is based upon the assumption that for any drainage area all hydrographs resulting from isolated storms of a given duration have the same shape when reduced proportionally to correspond to the same volume of run-off. Table 8 (Columns (1) and (2)) clearly indicates that the shape of the hydrograph may be decidedly influenced by the different capacities of the soil, although the duration of the rain, the shape of the drainage area, and the depth of the rain are exactly the same.

The mathematical theory shows that the concept of the unit hydrograph is practically applicable when: (1) The concentration time is appreciably greater than the duration of the rain and the drainage area is of such shape that the crest cannot precede the concentration times; and (2) the duration of the rain is appreciably greater than the concentration time, regardless of the shape of the drainage area. Under other conditions, the application of the unit hydrograph will not yield reliable results.

TABLE 8.—INFLUENCE OF SOIL CAPACITY ON TIME OF CREST

Capacity of soil, in hours	RECTANGULAR DRAINAGE AREA				TRIANGULAR DRAINAGE AREA			
	DURATION, FIFTY HOURS		DURATION, FIVE HOURS		DURATION, FIFTY HOURS		DURATION, FIVE HOURS	
	Time of crest, in hours	Maximum discharge in mile-inches per hour	Time of crest, in hours	Maximum discharge in mile-inches per hour	Time of crest, in hours	Maximum discharge in mile-inches per hour	Time of crest, in hours	Maximum discharge in mile-inches per hour
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
10	55.89	862.2	50.04	99.2	51.79	929.7	20.52	127.9
20	63.02	739.6	50.46	90.8	55.26	800.7	27.61	99.6
40	71.54	569.2	51.50	70.0	61.16	603.4	34.95	70.2
50	74.49	510.2	51.90	62.0	63.30	538.8	37.19	61.2

The influence of the time of the crest and the capacity of the soil upon the magnitude of the maximum discharge is also great. Column (3), Table 8, illustrates the corresponding values of the maximum discharge from a rectangular drainage area of 10 000 sq miles and 200 miles in length, and for a rate of rainfall of 0.10 in. per hr. These maximum discharges are computed from the formula

$$y_c = W\, r[L - v\,(t_c - t_0)] \dots\dots\dots\dots\dots\dots (24)$$

in which r is the rate of rainfall, and W is the width of the drainage area. In the foregoing cases, had the rain continued sufficiently long to bring the entire drainage area to a steady state (which, necessarily, would be longer than the time necessary to bring an individual unit to a steady state) the discharge clearly would be 1 000 mile-in. per hr.

The discharges for the corresponding capacities are expressed in mile-inches per hour, and 1 mile-in. per hr can be converted to cubic feet per second, thus:

$$1 \text{ mile-in. per hr} = \frac{5\,280 \times 5\,280}{12 \times 60 \times 60} \text{ or } 645.3 \text{ cu ft per sec.}$$

For short rains, the time of the crest does not vary appreciably with a varying capacity of the soil, provided the shape of the drainage area does not permit the time of the crest to precede the concentration time, but there still will be an appreciable variation in the maximum discharge. Thus for the same conditions that were outlined for Columns (2) and (3), but for a rain of only five hours' duration instead of fifty hours' duration, the corresponding values are shown in Columns (4) and (5), Table 8.

It should be emphasized that for Columns (2) to (5), Table 8, the rate of rainfall is the same, namely, 0.10 in. per hr. For Columns (2) and (3) the duration is 50 hr, so that the rainfall is 5.00 in.; and, for Columns (4) and (5), the duration is only 5 hr, so that the rainfall is only 0.50 in. Evaporation after the rain stops has been neglected, but formulas to correct the maximum discharge for this evaporation are readily obtainable.

By changing the shape of the drainage area, different values again result. Equations (23) and (24) are applicable only to a rectangular drainage area.[20] For a drainage area with a width $W(x)$, in which x is the distance above the gage and $W(x)$ a function that can approximate the histogram of the drainage area as closely as desired, the maximum discharge is given by

$$y_c = r \int_{v(t_c - t_o)}^{L} W(x)\, dx \dots\dots\dots\dots\dots\dots\dots (25)$$

for a duration of rain exceeding the concentration time regardless of the shape of the drainage area, and also for short rains if the drainage area is fan-shaped; or by a similar integral with upper limit $v\,t_c$, if the duration of the rain is less than the concentration time and the width of the drainage area decreases with increasing distance above the gage. Naturally, Equation (25) requires modification to apply it to varying conditions of soil capacity, rates of rainfall, and velocity of water.

To illustrate further how different soil capacities give rise to hydrographs of different shapes for the same drainage area, even if the rain is uniform throughout its duration, consider a hypothetical triangular drainage area, also of 10 000 sq miles.[20] For a long rain, duration of 50 hr, the appropriate formulas indicate the values given in Columns (6) and (7), Table 8. For a short rain, duration of 5 hr, the time of the crest precedes the concentration time, with the results shown in Columns (8) and (9).

MERRILL BERNARD,[21] M. AM. SOC. C. E. (by letter).—The unit hydrograph, as presented by Mr. Sherman[2] in 1932, has sustained itself well as the basis of a rational theory of relationship between rainfall and stream flow and as a practical tool for the solution of important hydrologic problems that previously had depended largely upon restricted, inflexible, empirical methods. Contributions following Mr. Sherman's introduction of the idea, including that of the author, have injected refinements into the technique and have added to the general knowledge of basic hydrologic relationships.

---

[20] "Run-Off—Rational Run-Off Formulas," by R. L. Gregory and C. E. Arnold, Assoc. Members, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), Fig. 5, p. 1068.

[21] Chf., River and Flood Div., U. S. Weather Bureau, Washington, D. C.

The stimulus given the field of applied hydrology by the unit hydrograph concept has created general dissatisfaction among hydrologists with the basic precipitation data, emphasizing, as it has, the inapplicability of average 24-hr rainfall to problems on the smaller water-sheds. The result can be expected, in the near future, to take the form of co-operative effort toward a network of recording rain gages over the United States, the beginning of which is evidenced in the 140 such stations established in 1937 by the Commonwealth of Pennsylvania.

The paper by Mr. Meyer has merit in a freshness of viewpoint, in the successful attempt to express the hydrograph of stream flow mathematically, and in the demonstration of the need for refinement in basic hydrologic data.

Refinement in method, as the writer conceives it, must evidence itself in two ways: (1) By producing consistently better agreement between computed and observed values; and (2) by adhering more rationally to the phases of the natural phenomenon of stream flow produced by surface run-off from rainfall.

The mathematical synthesis of the hydrograph has a definite place in this field, for the hydrograph is, in fact, a series of related curves capable of being expressed by three or more mathematical equations, the factors in which can be taken to represent the causes that combine to produce the hydrograph. A fuller understanding of the theory will depend upon the ability of hydrologists to inject greater detail into analysis, the confirmation of which must await the availability of correspondingly refined data.

Considering a practical relation between the adopted unit of time and the area of a water-shed, the degree of refinement will vary directly with the reduction of the time unit and will be proportional to the extent that the variation in rainfall over the water-shed and throughout time can be taken into account. Another source of appreciable error which, it is hoped, may be removed soon, lies in the inability of hydrologists to separate, accurately, the stream flow produced by surface run-off from that originating in ground-water sources.

It is difficult to associate the author's aims with his generalized assumptions. One can agree that total storm rainfall and total storm run-off may be expressed as a ratio. However, as far as the writer knows, the only approximate percentage through time is that existing between rainfall and the hydrograph of flow after the rainfall has been distributed as it will contribute to the flow at the outlet (the pluviagraph), and not in the order of its fall. It is more likely that refinement will take the course of dealing with the losses to run-off as a deduction from rainfall than as a ratio of run-off and rainfall.

Before continuing an examination into the author's work, it seems desirable to consider the least understood and most loosely expressed factor entering the synthesis of the hydrograph from rainfall—"concentration time." In its first conception this was considered to be the time in transit (based on the average velocity of flow) from the most remote point of the water-shed to the outlet. Later it was conceded that distance from the remote point to the outlet must be measured in units of time rather than in units of length; so that now "concentration time" is more generally understood to be the time interval at the end of which all parts of the water-shed are contributing to peak flow. In unit-hydrograph studies the concentration period is shown as the time interval between the respective centers of mass rainfall and resulting hydrograph, which is closely related to the peak ordinate of the hydrograph.

The author describes the time of concentration as that at the end of which the run-off becomes constant. Does he mean run-off (inflow) into storage, or discharge (outflow) out of storage? If he means the former, it would seem that wide fluctuations in the rate of rainfall must preclude the possibility of inflow prevailing at a constant rate for any appreciable time. If he means the latter, the assertion is not borne out in the shape of the normal hydrograph.

First, it must be understood that the concentration period cannot be a constant factor on any water-shed; it must vary according to the limits fixed by surface cover, the channel characteristics of the collecting system, and the distribution of rainfall over the area. Time of travel through the system of channels varies inversely with depth and effective hydraulic radii, fair stability being reached in both average velocity and wave velocity as bankful stages are approached.

If the time of concentration is considered to be that at the end of which all parts of the water-shed are contributing to peak flow, one must still be critical, because it is known that on a particular basin rainfall may be so favorably concentrated over the lower principal tributaries as to create the peak of the hydrograph before outlying areas have produced and delivered effective quantities of run-off to the outlet. Particularly on larger basins it is probable that surface retention and retardation will prevent contributory flow from appreciable areas during the peak stage, withholding their contribution to sustain the hydrograph in its recessional phase.

The writer has felt for some time that there is definite place for observational research in any plans there may be, in order to refine one's knowledge of rainfall-run-off relationships; and it seems to him that, with a little exercise of the imagination, the phenomenon of flow assembly can be explained as follows:

Select a unit of area on a natural water-shed of such size that a detailed view of the whole may be had from a central position, say, an acre. Take a position at the beginning of a downpour and note that the water at first soaks into the ground. Water begins to accumulate in the depressions and soon overflows and combines into a system of heretofore indiscernible small channels. The run-off from the unit area accumulates rapidly at the lowest corner where it enters a small, but well-defined, channel. The map of the water-shed indicates plainly the course the water will take to reach the outlet.

On another occasion one will observe an application of rainfall throughout a unit of time to the unit of area. Where, in the previous experience, the ground at the beginning of the rain was quite dry, with a resulting prolongation of the period necessary to satisfy the infiltration capacity of the soil, in this case antecedent rainfall has largely satisfied this initial condition, so that the run-off begins quickly, and assembles and discharges at a higher rate than before.

The observer visits his unit of area on numerous occasions and notes that, although there are obvious differences in the amount, and in the rapidity with which run-off flows to the outlet and joins the flow in the small outfall channel, there is a marked stability in the regimen of flow assembly. Run-off begins, combines, discharges from the area, and reaches the outlet in about the same manner from each rainfall of unit-time duration.

It is not difficult, then, to envision a water-shed comprised of unit areas which are related in the common characteristic of the time taken by their run-off waters to reach the outlet. In a natural water-shed these units would arrange themselves with reasonable continuity along lines conforming fairly well to surface contours. The isochrons, or "time contours," would differ from the surface contours in that, whereas the latter would be roughly parallel and would reach up into the principal tributaries of the system, the isochrons would be foreshortened because of the much higher rate of travel of the water after it has reached the principal channels.

To organize a mind picture of the process along these lines consider:

(1) A water-shed reflecting normal regional characteristics;

(2) A surface contour entering the water-shed at a line normal to the outlet;

(3) An isochron connecting the outlets of contiguous unit-areas entering the water-shed at the same point as the surface contour but bearing down-slope as it continues into the water-shed in order to maintain a constant delivery period (thus it provides for the obvious necessity of reducing the distance from the unit-area to the channel system in a direction normal to the latter in order to compensate for time of travel through the channels to the outlet); and,

(4) A map of water-shed, developed through acceptable analytical procedure (and based, if possible, on observational data) showing the unit-areas having a common time of travel from their outlets to that of the water-shed arranged along isochrons at fixed-time intervals, as the hour.

Concentration time may be expressed as the time required by the first water leaving a series of unit-areas along an isochron to reach the outlet; or it may be considered as the time taken by a series of unit-areas to discharge, completely, the run-off resulting from a unit-time rainfall. It is better understood as an enveloping line of equal time under which all of the units are contributing to the flow at the outlet within the period designated by the isochron. If the map shows lines of equal time of concentration at hourly intervals, and the areas progressively enveloped by each are determined, one can say that at the end of the first hour so many acres will be contributing to the flow at the outlet; at the end of the second hour so many more units, or a total of so many units will be contributing—and so on to the outer limits of the water-shed. Thus, in the isochronal map, one discerns the principal reason for the constancy in the time-base of a hydrograph resulting from rainfall confined to a unit of time.

The unit hydrograph has at least three phases—the rising, the peak, and the recessional. Thus far this discussion has had to do with the rising and peak stages. The rise is accounted for by the fact that the flow at the outlet is increasing because of (*a*) an increasing depth over the unit-areas already contributing to the outlet flow, and (*b*) an increasing contributing area. The latter influence on accelerated flow is removed when elapsed time has progressed upward and over the isochronal map to the outer limits of the water-shed. If the cessation of rain is coincident with the end of this time-period the result is a unit hydrograph as conceived by Mr. Meyer. There are two conditions, however, that must be satisfied before the analyst can be assured that the hydrograph will peak at, or shortly after, this time interval, and not before. First, the water-shed and the collection system must have fair uniformity in shape and in pattern. That is, the isochrons must be fairly regularly spaced and not concentrated around several important contributory branches discharging near the outlet and thus leaving appreciable areas at the outer limits of the water-shed to be represented by widely spaced and comparatively few isochrons. Second, the rainfall must be uniform throughout the time interval and over the water-shed; because, if normal variations are considered, it is obvious that heavy concentrations in the early part of the period and over the lower part of the water-shed will create the peak of the hydrograph before the more remote parts are contributing. Continuing rainfall will build up a gradual increase through the peak phase until a period of rainfall equal to the time-base of the unit hydrograph has passed, after which the peak will increase or decrease with the fluctuations in rainfall intensities to the end of the rainfall period. The hydrograph now starts downward through the recessional phase which constitutes withdrawal from the water in storage in the channel system.

Concentration time has been discussed as if it were a constant characteristic of a water-shed. This is true only within limits that are believed to be relatively unimportant when other errors inherent in hydrologic data themselves are taken into account. Variations in the concentration period are attributable to the following causes:

(1) Seasonal and developmental changes in vegetal cover of the water-shed affecting the quantity and rapidity of run-off;

(2) Seasonal changes in bank and channel growth affecting the movement of water in the channel system;

(3) The initial depth of water in the channels at the beginning of run-off; and,

(4) Variations in the distribution of rainfall over the water-shed as these variations affect the assembly of flow and propagation of the flood wave which delineates the hydrograph at the outlet of the water-shed.

If the actual condition of flow during a period of flood run-off is considered, one can appreciate the inappropriateness of applying average velocities to the moving water. The synchronization of flow assembly on a drainage area of fixed regimen varies only slightly from flood period to flood period—a fact which finds support in the similarity in shape of unit hydrographs of a particular water-shed.

Likewise, the conditions of the storage equation must be met (that is, within a unit of time, inflow plus or minus changes in storage must equal outflow). Inflow is a highly variable factor, being the sum of innumerable and widely varying contributions to flow discharging into channel storage along both banks of the entire channel system. Outflow is much less erratic in fluctuation, rising to and receding from a crest stage with the regularity of a compounded mathematical curve. Therefore, the balance demanded by the storage equation must be maintained by rapid changes in the configuration of the storage volume, creating irregularities in hydraulic slope and channel section which are recognized as characteristic of transitional waves.

FRANKLIN F. SNYDER,[22] JUN. AM. SOC. C. E. (by letter).—A "revision of current methods for the determination of stream flow from rainfall" is presented in this paper. The author uses time of concentration (defined as length of time until run-off becomes constant from a continuous rain of constant intensity) and a basic hydrograph to define the run-off characteristics of drainage basins.

The writer will show that if the user of the unit hydrograph and the user of the basic hydrograph could agree on the time of concentration for any area, the latter would be identical with the former as obtained by use of a unit hydrograph under the same assumptions. Of course, this would require that the agreed time of concentration be equal to the duration of surface run-off from a short duration or instantaneous storm, and would be a different quantity from that used in the rational method of sewer design.

Definitions not given by the author are required, with the introduction of the term, "surface run-off" or "flood run-off," as distinguished from "ground-water run-off." "Surface run-off" is usually defined as storm water that reaches the open drainage channels without penetrating the ground surface; but, the separation of surface run-off from ground-water run-off is usually made on hydrographs by drawing a horizontal or slightly inclined base flow line under the flood rise. The base flow rate is usually fixed by a low value of the stream flow previous to the flood rise. The time involved for the duration of surface run-off varies approximately from three to ten days for areas of from 10 to 10 000 sq miles. The flood run-off thus obtained may, or may not, fit the definition.

Table 9 gives a two-hour unit hydrograph derived by synthetic procedure[16] for the stream flow station of the U. S. Geological Survey at Big Piney Run near Salisbury, Pa. (drainage area equals 24.5 sq miles). The ordinates as tabulated are for the end of the designated two-hour periods. Fig. 11 shows the two-hour unit hydrograph and the cumulative plotting of the two-hour ordinates of the unit hydrograph, which is the run-off graph computed with the two-hour unit hydrograph for a continuous rain of 1 in. per 2 hr (100% run-off). This, then, is the basic hydrograph for the area according to the unit hydrograph procedure. To show that Fig. 11 is independent of the unit of time, Table 9 also gives the four-hour unit hydrograph for the same area. This hydrograph is the two-item progressive average of the two-hour unit hydrograph. The six-hour unit hydrograph would be the three-item progressive average of the two-hour unit hydrograph, etc.

---

[22] Associate Hydrologic Engr., U. S. Weather Bureau, Pittsburgh, Pa.

It should be emphasized that if an area is such that satisfactory results can be obtained with a unit hydrograph for four-hour rainfall quantities, the four-hour unit hydrograph ordinates would usually be tabulated at intervals of four hours rather than two hours as in Table 9. However, there is no reason why two-hour ordinates cannot be used with rainfall tabulated every four hours.

* 1 650 at seventh hour. † Recession coefficient of 0.92 applicable after twentieth hour.

The continuous rain of 1 in. per 2 hr (in this case 2 in. per 4 hr) can be distributed with the four-hour unit hydrograph by the usual procedure of tabulating the product of the unit rainfall, times the unit hydrograph ordinates in vertical columns and adding horizontally for the totals. The hydrograph obtained is exactly the same as the basic hydrograph defined with the two-hour unit hydrograph. The same result would be obtained from a six-hour unit hydrograph and a continuous rain of 3 in. per 6 hr.

The time of concentration by the foregoing procedure is 88 hr, although the last two days do not increase the discharge very much. The basic hydrograph obtained from the two-hour unit hydrograph (run-off graph of a two-hour storm) and the author's method of synthesis is shown in Fig. 11. The author's values of λ, given in Table 1 of the paper, were used with ordinates of the two-hour unit hydrograph at 1-hr intervals. The procedure failed to define the concentration curve above a value of 6 245 cu ft per sec, so what was considered a reasonable extension was made and is shown by a broken line in Fig. 11.

This comparison shows the considerable discrepancy between the two procedures due to the fact that the author's time of concentration is evidently much less than the duration of unit hydrographs as ordinarily used.

If the run-off (which is usually called "flood run-off") were true surface run-off as previously defined, the time of concentration of 12 hr, and the basic hydrograph as obtained with the author's procedure, would probably be a true picture of what occurs. However, much of the run-off which at present is called surface run-off is not true surface run-off as previously defined; it is sub-surface storm flow which penetrated the surface of the ground on its way to the drainage channels, but did not reach the stable ground-water table. The recession sides of unit hydrographs are storage depletions, but not from channels alone. In other words, part of the run-off from every unit of rainfall is destined to pass through this temporary ground storage and reach the gaging station later than would satisfy a reasonable value of time of concentration as used in the rational method.

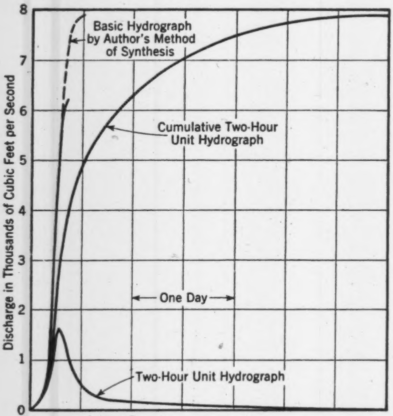

FIG. 11.—BASIC HYDROGRAPHS FOR BIG PINEY RUN NEAR SALISBURY, PA.

Eventually it may be necessary to separate the true surface run-off from sub-surface storm flow and ground-water discharge since it appears probable that there is a limit to the sub-surface storm-water storage and flow for any particular drainage basin. Thus, in very large floods, due to the maximum being reached or a limit set by existing infiltration capacity, a greater percentage of the total flood run-off occurs as true surface run-off as compared to sub-surface storm flow. This gives a unit hydrograph with an earlier and higher peak and less volume in the recession side than is the case in ordinary floods. This difficulty requires special adjustments in the unit hydrograph procedure and would probably require similar adjustments in the use of a basic hydrograph.

Fig. 12, showing the rainfall and run-off records for the storm of October 27 and 28, 1937, on Big Piney Run, illustrates the foregoing discussion.

A rational time of concentration for the small head-water area, whose longest channel is eight miles with a drop of 300 ft, would not be more than four hours at the maximum. The lag for the area, which is believed to be a more important hydrologic characteristic of a natural drainage basin than time of concentration, is about six hours. Lag is defined as time from center of mass of surface run-off producing rain to peak discharge and tends to be a constant for any drainage basin.

The U. S. Geological Survey topographical maps show some swamp area bordering on the two main channels, but in general the topography is quite rough, with a range in elevation from 2 800 to 2 200 ft. It is felt that the swamp areas might be the cause of as much as one hour out of the observed 6-hr lag for the area.

The Big Piney recording rain and snow gage, located on the Big Piney Run Basin, shows a continuous rain of 18 hr of fairly constant intensity, preceded by several short periods of precipitation and followed by 12 hr of precipitation at a lower but fairly constant rate; yet the discharge hydrograph shows no tendency toward a constant discharge at the crest. As a matter of fact, the unit hydrograph procedure for this storm gives a flatter crest than the observed record due to the rainfall of decreasing intensity at the end of the storm.

Fig. 12 shows the discharge hydrograph computed from the basin rainfall with the two-hour unit hydrograph previously given. Table 10 shows the two-hour quantities of precipitation and surface run-off and the distributions for a few of the items. The computations were shortened through the use of a surface run-off recession coefficient and the addition of a composite column which includes the recessions of discharge of all 2-hr items that have passed the twentieth hour. The increasing percentage of run-off was based on rainfall-run-off relations used in forecasting work in which ground-water discharge is used as the index of run-off conditions.

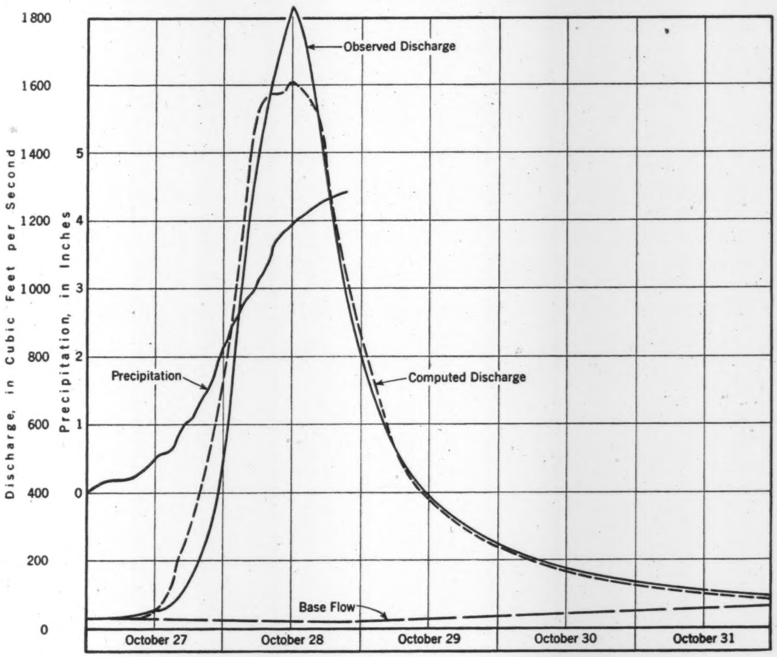

FIG. 12.—FLOOD OF OCTOBER 1937 ON BIG PINEY RUN

It would appear from a study of this storm that any basic hydrograph that would reproduce the discharge hydrograph would have to be quite similar to that obtainable from the unit hydrograph.

Assuming that a basic hydrograph can be agreed upon for any area, there are several weaknesses in its analysis and synthesis as given by the author. If a time of concentration of 12 hr is assumed for the drainage basin whose basic hydrograph is developed in Fig. 2, it is seen that the time of peak discharge is earlier for the 7-hr rain than for the 1-hr rain. The possibility of such an occurrence seems very slight.

† The distributions are omitted for the items of run-off from 4 P.M., October 27 to 6 A.M., October 28, and for the items after 2 P.M., October 28.

Another point is the fact that if rain ceases after some unit area, say the sixth, has contributed its *h*-value at the gage, the author's procedure immediately begins to decrease the ordinate of discharge contributed at the gage by this area which is six units of time away from the gage. This means that the five units of flow from the area which have already started their trip through the drainage system are decreased simply because it stops raining.

The author's use of a recession coefficient is very timely. This coefficient eliminates about two-thirds of the work involved in unit hydrograph computations.

The author's illustration of the fact that ground-water discharge is a reliable index of run-off conditions is to be commended. However, the statement that ground-water flow has no characteristics to identify it with any particular period of precipitation is not so acceptable. If ground-water discharge is to be used as a successful index of run-off conditions, a well-defined procedure must be available for delineating ground-water discharge. It is difficult to accept time of the year as a satisfactory medium for this purpose. Ground-water depletion and storage curves provide a ready means of identifying, quantitatively, the ground-water discharge or recharge with particular periods of precipitation.

The statement that the unit hydrograph procedure and a continuous rain will frequently give a run-off rate exceeding the product of the rainfall rate and the percentage of run-off is difficult to understand. The continuous rain of 1 in. per 2 hr and the two-hour unit hydrograph for Big Piney Run give a peak discharge (100% run-off) of 7 915 cu ft per sec which is, of course, a run-off rate equal to the rainfall rate of 0.5 in. per hr.

In considering the probable accuracy of the author's synthesis of a hydrograph as compared with the unit hydrograph procedure, especially in flood forecasting, it is doubtful whether the proposed methods are far superior to the unit hydrograph procedure. It has been the writer's experience that the three main problems in computing an accurate discharge hydrograph from rainfall are the rainfall itself, the quantity of run-off that will occur, and the shaping up of the run-off.

Of the three, the possible rainfall eccentricities provide the most trouble, and the shaping up of the discharge hydrograph is the easiest to accomplish. By this, it is not meant to infer that the assumption of a uniformly distributed rain of constant intensity might not be the best for certain flood control studies. In comparing the flood reduction benefits available at some particular point from reservoirs at various locations, it may be more desirable to have a consistent procedure rather than to duplicate probable quantitative occurrences.

W. G. HOYT,[23] M. AM. SOC. C. E. (by letter).—Through detailed analyses, such as described by the author, a mass of valuable information is gradually being accumulated relating to the characteristics of surface run-off resulting from precipitation in the form of rain. It appears that at present the application of the unit graph and similar methods, such as that described by the author, must be largely confined to problems involving flood run-off resulting from rain, and to areas where the run-off reaches stream channels essentially as over-land flow. In the eastern part of the United States its application to flood problems during periods of no snow has been demonstrated amply. Unsatisfactory results may be obtained, however, if application is attempted in areas or periods when the flood run-off results largely from melting snow, or in areas where the greater part of the stream discharge reaches channels through the ground. Under such conditions failure to substantiate earlier findings may be attributed erroneously to flaws in basic principles, whereas the difficulties may relate to a lack of knowledge regarding the behavior of run-off that may reach a stream through the ground with a responsiveness approaching that of direct surface run-off.

---

[23] Hydr. Engr. (Prin.), Conservation Branch, U. S. Geological Survey, Washington, D. C.

Most of the basic data underlying the theory of the unit graph, the basic hydrograph described by the author and, in fact, much of the present knowledge relating to the flood run-off have been based on observations made in the north-central and northeastern parts of the United States. In these regions, relatively: (*a*) The greater part of the flood flow is essentially direct surface run-off; (*b*) infiltration rates and retention capacities over large areas, during major flood periods, are relatively small; and (*c*) periods involving large quantities of melting snow are generally found inapplicable for study. It is only natural that some modification in principles thus derived may be necessary before they are applicable in parts of the central and much of the western part of the United States. In this latter region, flood run-off—especially from the Sierra Nevada, Rocky, and northern coast range mountains—is largely associated with run-off from melting snow; and, in the southern coast range and semi-desert regions, infiltration rates and retention capacities, in general, are apparently very high, and only a small part of the storm precipitation reaches stream channels as direct over-land flow.

It is in the latter areas, especially, that much more hydrologic research with reference to flood run-off is urgently needed.

C. O. CLARK,[24] JUN. AM. SOC. C. E. (by letter).—In bringing to the attention of hydrologists the alteration of the hydrograph effected by channel storage, Mr. Meyer points to an agent ordinarily considered to be small, but an understanding of which is essential to one striving to avoid misuse of the unit hydrograph, and to reproduce or predict stream flow with greater accuracy.

Any one wishing to make a more extensive investigation into this problem will find the theory expressed in the Muskingum method of flood routing a valuable tool for correlating Mr. Meyer's analysis of the hydrograph with the familiar function of storage in the usual routing of floods.

The writer is familiar with no generally available publication which explains this method, but reference to it, and definition of terms, have been made by T. T. Knappen,[25] M. Am. Soc. C. E. The terminology used by Mr. Knappen is adopted herein, and the formula is not repeated.

Further development of the flood routing equation shows, in addition to the explanation in the aforementioned discussion, that

$$o_2 = C_3\, i_2 + C_4\, i_1 + C_5\, o_1 \qquad (26)$$

---

[24] Asst. Engr., U. S. Engr. Office, Norfolk, Va.

[25] "National Aspects of Flood Control: A Symposium," *Transactions*, Am. Soc. C. E., Vol. 103 (1938), Equation (3), p. 667.

in which

$$C_3 = -\frac{K\,x - 0.5\,T}{K - K\,x + 0.5\,T} \qquad \text{(27a)}$$

$$C_4 = +\frac{K\,x + 0.5\,T}{K - K\,x + 0.5\,T} \qquad \text{(27b)}$$

and,

$$C_5 = +\frac{K - K\,x - 0.5\,T}{K - K\,x + 0.5\,T} \qquad \text{(27c)}$$

It will be noted that C_5 is the same as the author's "λ," when $x = 0$—that is, when storage is solely a function of discharge. By analyzing the falling hydrograph, one can determine the value of K, which is the differential of the storage-discharge equation, and which, when storage varies directly with discharge, is the author's C_2. Knowing the value of K, and its variation with discharge, one can determine a storage-discharge curve, about which storage studies revolve, regardless of whether the ratio of total storage to instantaneous discharge is a constant or not, as long as the variation of the ratio is uniform. It will be seen that the assumption of direct variation is not necessary, except where the convenience of use outweighs the desirability of accuracy, or where the quality of fundamental data does not warrant the refinement of considering the variation. The writer is of the opinion that the assumption of uniform variation is sufficiently correct on many, and most, streams to warrant calculations on that basis except where reliable hourly records of rainfall are available. The graphical methods in use in routing floods through reservoirs, or reaches where storage is a function of discharge stage, will be found applicable and convenient.

The greatest advantage of studying the hydrograph with this tool may prove to be the indication that the storage in the ground-water table may be correlated with stream discharge stage and thereby enable one to use values of run-off that will be not less than the monthly average run-off, without resort to the somewhat confusing and highly artificial concept of variable base flow. For example, on a particular stream, with a drainage area of about 1 300 sq miles and 75 miles maximum length, the minimum value of "K" on the falling limb of several hydrographs of varying size, and from rainfall of various intensities and duration, appeared to be fairly constant at about 8.0 hr, but below a discharge of 6 cu ft per sec per sq mile the values were greater and had a common trend, but were not strictly uniform. The larger values were approximately 200 hr.

Detailed analysis showed that the variation could be explained and duplicated closely by a compound unit graph, the sum of two simple hydrographs, one of surface run-off and one of sub-surface run-off. The surface run-off, taken as 70% of the total run-off, was assumed to contribute according to the author's histogram, routed through channel storage of 8.0 hr by the Muskingum method. The sub-surface run-off (30% of the total run-off) was taken as contribution by the histogram routed through 200 hr of storage. These two hydrographs, added together, make up a compound unit hydrograph which has all of the advantages that the author claims for his basic hydrograph, and does not need to be used with a variable base flow to secure reasonably accurate and consistent results for the entire hydrograph, using percentages of run-off highly consistent with the monthly average run-off, base flow included. It will be apparent that the unit hydrograph is almost the same as the author's basic hydrograph for surface run-off plus another for sub-surface run-off. As Mr. Meyer states, the bases are infinite, but may be used as constant, of such length as will include 95% to 98% of the volume, without appreciable error.

Confining attention to the constant storage-discharge relation assumed by the author, the writer finds little difference between the unit hydrograph and the author's basic hydrograph, and therefore uses the terms interchangeably. A unit hydrograph that has been routed through such channel storage above the gage has the infinite base length to which the author refers, may be applied to variable quantities of run-off in successive unit periods of time, and will provide a more accurate indication of discharge than can be justified in the use of the usually available rainfall records. The well-derived unit hydrograph will show the effect of constant-ratio storage and is only less accurate than the author's method in that very small ordinates are conveniently neglected, for the sake of ease in computation, and a constant base length of hydrograph results. The lack of agreement between the new method and the old method in computing the hydrographs of the Merrimac River, shown in Fig. 7, could only result because the unit hydrograph used was not as well derived as the basic hydrograph. Although the writer has not proved that this statement is true algebraically, he has proved it to his satisfaction by routing hydrographs of various shapes through reaches of constant storage-discharge relation to prove that the sum of the separately routed hydrographs is equal to the routed hydrograph of the sum of the separate hydrographs.

The use of the concentration curve and the storage curve to derive the unit or basic hydrograph of an area has very real value. To be consistent, however, it would appear that the rising curve should show the effect of storage, because the same storage which holds the hydrograph up on the falling leg holds it down on the rising leg and accounts for much of the lag between initial rainfall and initial rapid rise of the stream.

The writer would like to raise one question with regard to the use of the histogram. If the contribution of the areas of varying distance from the gage combine to form the concentration curve, does it not necessarily follow that the contribution to the channel must fall off in the same manner? The writer has found hydrographs which exhibit the very rapidly falling leg and the angular break near the peak; but those found resulted from rainfall of several periods of duration which terminated in a short period of extremely intense rainfall, rather than, as the author suggests, from a prolonged rainfall of fairly uniform intensity.

The author's derivation of time of travel and, therefrom, the concentration time of a given area, will be useful in a system of rivers which has followed a fairly uniform geological formation (such as the Mississippi System), because there is a general symmetry within the basin; but this concept must be used with caution in river systems which have developed through much stream piracy, because in these may be found slopes in head-water streams which are less than the slopes in the main stream, near the mouth. This condition is quite common in streams in the South Atlantic Coast areas. Of course, the latter type may not meet the author's criteria for similar streams.

The analysis of stream run-off is susceptible of much more accurate computation than has yet been applied to it; by combining the concept of storage modification and the unit or basic hydrograph, degrees of accuracy in computation may be obtained, for many areas, which are limited at the present time by lack of hourly rainfall records. The increase in the number of such stations, and in recorder stream gages, will enable those who, like the author, are unwilling to accept the accepted methods, to delve into the problem and find the mechanism by which very high degrees of accuracy in discharge forecasting will be possible.

C. S. **Jarvis**,[26] M. Am. Soc. C. E. (by letter).—In the midst of the usual output of new plans hopefully aimed at refinements in run-off estimates, it is reassuring to find that the author, along with other proponents of new procedures, recognizes and admits the inherent limitations as to accuracy, and consequently the main dependence on logical reasoning, guided by mature experience, in any practical approach to evaluation of run-off factors and characteristics. Of all the divergent curves in Fig. 4, for instance, it is expected that appropriate choice shall be made after sufficient experience and with the aid of detailed topographic maps of the drainage area. However, the limitless variations in rainfall patterns, widely departing from what may have been adopted as the basis of reckoning, are capable of producing some very erratic results.

The writer has attempted to meet a requirement in the field of quantitative appraisal of run-off characteristics as they might be influenced by land-surface treatments and other soil and water conservation measures. The preliminary results are depicted in Fig. 13 and are held as only tentative, pending the completion of a more detailed analysis involving more rigorous procedure and a more nearly scientific approach. The agreement resulting from the two methods was so marked as to establish the preliminary solution nearly on a par with the final result.

Among the assumptions involved in both approaches to this problem were the following:

(1) Retention of rainfall by surface storage and induced infiltration on a representative portion of the drainage basin area, such as one-fourth or one-half, with no escape to drainage channels by over-land or other surface flow, must inevitably reduce the total volume of run-off within that flood-rise in about the same proportion;

(2) Reduction of run-off from similar areas by reason of detention works, increased vegetative cover, lengthened course of travel, reduced gradients as

---

[26] Hydr. Engr., SCS, Dept. of Agriculture, Washington, D. C.

well as velocities of flow, and prolonged contact of such water with the soil surface, account for a proportionate decrease of run-off volume; and,

(3) If the treated areas are widely distributed throughout the drainage basin, the base of the flood hydrograph could not conceivably be shortened as a result of such detention and retardation through conservation measures.

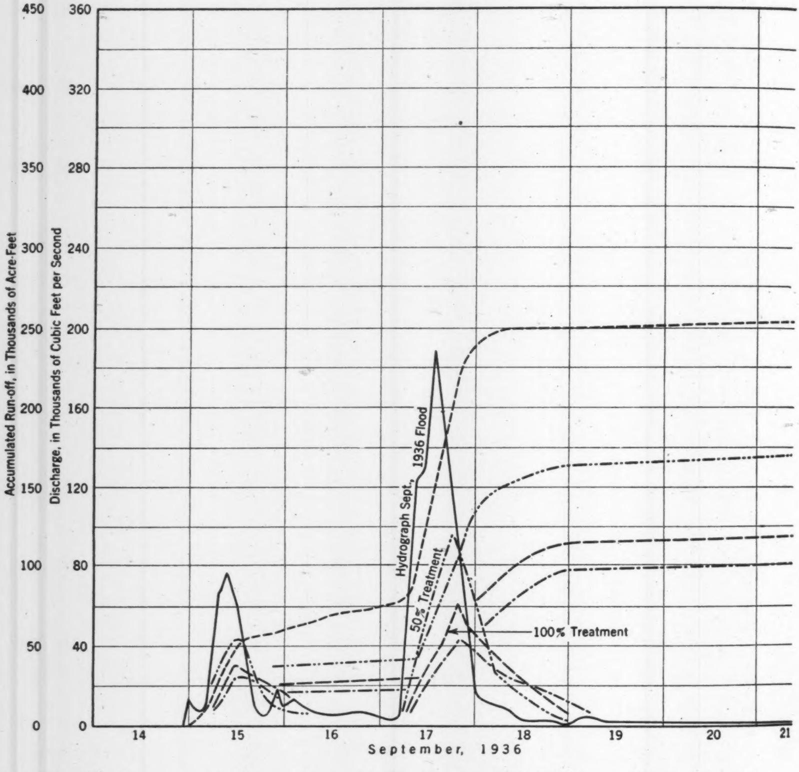

FIG. 13.—HYDROGRAPH AND MASS CURVE OF SEPTEMBER 1936 FLOOD ON NORTH CONCHO
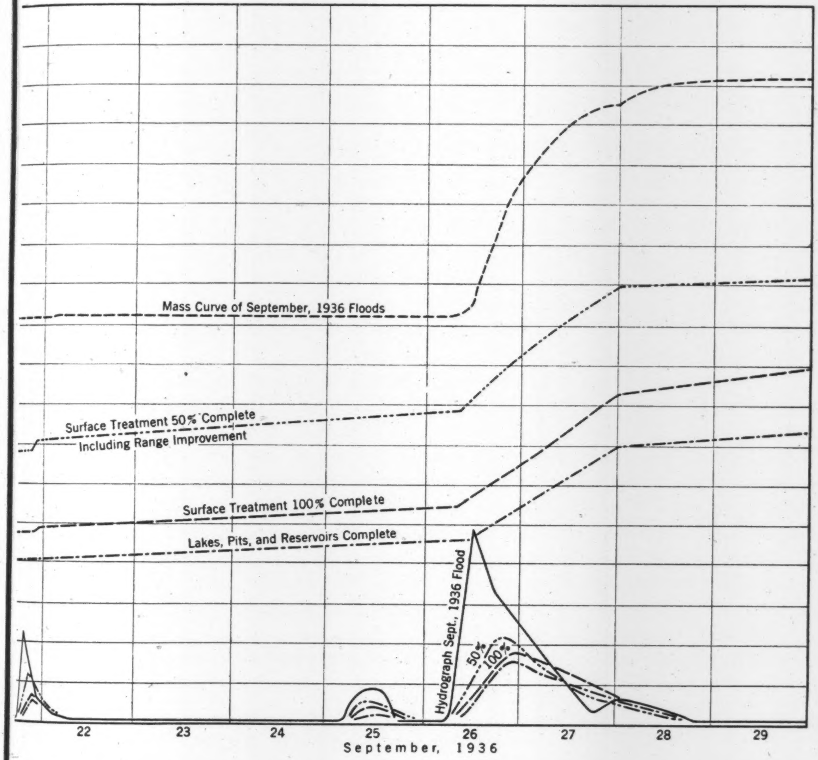
SIVE EFFECTS OF CONSERVATION MEA-

Due to the reduction in velocities of the component parts of the gathering flood, not only must the occurrence of the flood peak be delayed, but the base of the flood hydrograph must be lengthened. Then the peak discharge (shown graphically in Fig. 13 as the altitude of the triangular form of flood-rise) must necessarily be reduced in measurable amounts both by reason of such lengthening of the base and by reason of reduced flood volume, represented by area under the hydrograph. Thus, if the area of a triangle is reduced by half and the base remains unchanged, only one-half of the original altitude remains; but if the base is lengthened, the apex is lowered still farther.

Although some percentage of the retained rainfall may appear in the stream channel at some later time, to increase the low-water discharge, the contributions will probably be in the nature of springs or seeps, and generally will be of value in a water-utilization program.



River at San Angelo, Tex.; also, Revised Curves to Illustrate Estimated Progressures Applied to the Drainage Basin

It happens frequently that the apparent lack of hydrologic data may be mended in part by recourse to such procedures and methods of approach as are illustrated in the foregoing example. Briefly, the justification for subtracting a treated area from the rôle of storm run-off contributor depended on the following provision: That the sum of infiltration and available surface-storage depths should equal or exceed the depth of rainfall on that area for any given period. In this case, soil infiltration records covered a period of several years, and actual performance of level terraces, contour ridges and furrows, diversion and spreading works, and other aids to increased infiltration, under the record-breaking storm conditions of September, 1936, proved their effectiveness in regulating and reducing flood run-off.

HOWARD M. TURNER,[27] M. AM. SOC. C. E. (by letter).—A "basic hydrograph" is developed, in this interesting paper, which the author defines as the hydrograph resulting from a uniform rain with a duration equal to the time of concentration. A hydrograph for a storm of this length should be a characteristic one for each point. The use of a time unit of subdivisions of the time of concentration instead of days or hours is an interesting suggestion, and the hydrograph itself should prove a useful tool in hydrograph analysis. The author develops this hydrograph as consisting of only two parts, its rising limb (the concentration curve) and its falling limb (the storage curve). He states that there is a sharp break at the top which he has actually found on continuous gage records. Groups of hydrographs of the Pemigewasset River at Plymouth, N. H., reduced to comparative scale, are assembled in Fig. 1. It would be interesting to have the complete information regarding this particular hydrograph and the rainfall producing it.

The writer does not believe that the basic hydrograph given is one which will be produced on a river by a uniform rain storm just equaling the time of concentration, particularly in respect to the sharp break at the top where, in the author's description, the concentration curve changes immediately to the storage curve. This assumes that the stopping of the rainfall all over the water-shed is felt to its full extent immediately at the point of measurement. The writer cannot conceive that the shutting off of the water supply from the rainfall at distant points can possibly be felt so abruptly at the point of measurement, due to the effect of time lag and channel pondage in the entire stream system. The latter is such a powerful factor that it modifies changes in river flow, definitely, through lengths of ordinary channel not involving large storage. The writer has in mind several cases in which continuous stream-flow gagings are made at points a few miles below water-power plants. The sharp, vertical changes in flow at the plant due to closing the station become modified into curved hydrographs with rounded corners and sloping sides a short distance down stream, due to effect of channel pondage.

That this sharp break cannot occur on the "basic hydrograph," except perhaps on very small drainage areas or in very special cases, can be shown simply by dividing any area into its tributary parts. The writer has assumed for this purpose a drainage area as shown in Fig. 14. Any division of the drainage area into tributary areas would serve as well, the selection being purely arbitrary. These tributaries, being smaller than the main river at the point of measurement, must have shorter periods of concentration so that a storm lasting for the period of concentration for the entire area must extend beyond the periods of concentration of the smaller component areas. A storm beyond the concentration period will consist of a rising concentration curve up to the time of concentration. If the rain continues uniformly beyond this point, the hydrograph will have a horizontal top equal to the maximum reached at the time of concentration, and if the author's assumption is correct, when the rain stops the storage curve will begin with the sharp break he has described. In other words, for a storm longer than the concentration period, the hydrograph, according to the author's concept, must be the same as his basic hydrograph except that it will have a flat place at the top equal in length to the time that the rainfall exceeds the time of concentration.

---

[27] Cons. Engr., Boston, Mass.

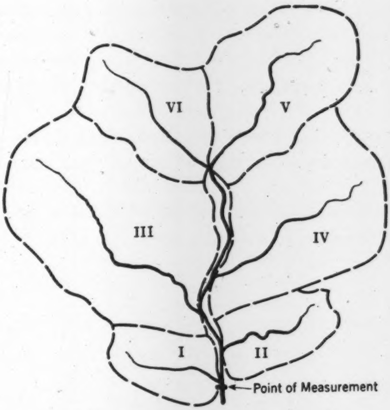


FIG. 14.—ASSUMED DRAINAGE AREA

On this basis the writer gives in Fig. 15 such flood hydrographs adapted from the author's basic hydrograph for the various subdivisions of the drainage area considered. These hydrographs of the tributaries are all drawn with similar "concentration curves" and corresponding "storage curves." They need not be uniform, of course, and in an actual case would not be so; but, on the author's assumption, they would present the general form given with the sharp break at the end of the rain.

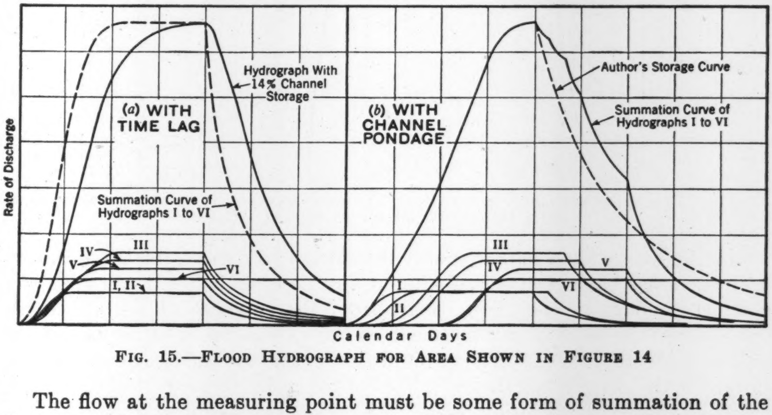

FIG. 15.—FLOOD HYDROGRAPH FOR AREA SHOWN IN FIGURE 14

The flow at the measuring point must be some form of summation of the flows from these separate drainage areas. The writer has combined them in two ways—one as shown in Fig. 15(*a*), allowing time lags for the water from each tributary to reach the point of measurement, and Fig. 15(*b*), allowing no time lag but assuming the main river, from the point of entrance of the uppermost tributaries to the point of measurement, is a pondage basin. In the latter case, water entering at any point of the basin would be felt immediately at the point of measurement—that is, the outlet of the basin. What actually happens is supposedly a combination of the two, with the storage-basin effect giving a decreasing time of transit along the main river as the river becomes more full. The two assumptions cover the extremes.

Considering Fig. 15(*a*), the descending limb of the curve is of a very different shape from the curve presented by the author. Because of the time lag required for the discharge from each tributary to reach the point of measurement, the storage curve does not begin sharply at the end of the storm. If the sharp curve does not exist at the point of measurement, neither does it exist on any of the tributaries, each of which may be similarly subdivided. If the tributary hydrographs do not have these sharp corners, the cusps in the combined hydrograph will disappear, and the curve will present a smooth descending limb, but with no sharp break.

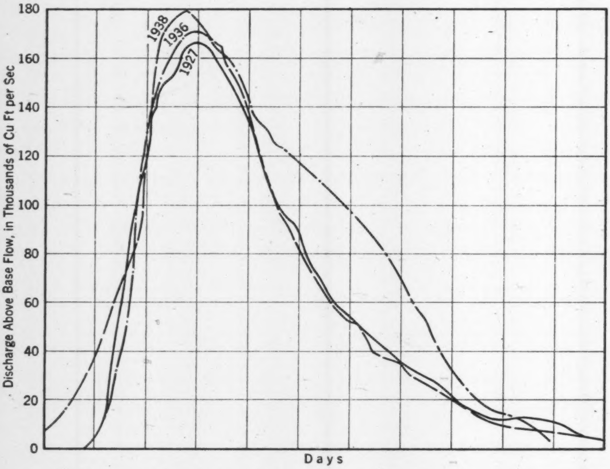

FIG. 16.—FLOOD HYDROGRAPHS ABOVE BASE FLOW—CONNECTICUT RIVER AT SUNDERLAND, 1927, AND MONTAGUE CITY, 1936 AND 1938

In the case shown in Fig. 15(*b*), the same hydrographs of the tributary drainage areas have been added without any time lag but with allowance for channel pondage in the main stream from the entrance of the uppermost tributary to the point of measurement, in this case assumed at the peak to be 14% of the total run-off. The effect of this storage is to give a convex curve, instead of the sharp break shown by the author, at the upper part of the hydrograph after the concentration period when the rain is assumed to stop. As in the case in the hydrograph shown in Fig. 15(*a*), if the tributary hydrographs do not have the sharp breaks shown by the author (which, by the same reasoning, they do not have) the descending limb in this case will depart still further from the author's.

It is not maintained that either the results shown in Fig. 15(*a*) or Fig. 15(*b*) represent the actual hydrograph for the assumed case, but neither of these hydrographs of the limiting cases shows the sharp break.

In the writer's opinion the flood hydrograph of a river is much less sensitive than many of the theories of hydrograph synthesis assume, due mostly to the effect of pondage in the entire system. As an example, Fig. 16 shows the flood hydrographs of the three large floods on the Connecticut River at Sunderland, Mass., in 1927 (8 000 sq miles of drainage area) and Montague City, Mass., in 1936 and 1938 (7 890 sq miles). The base flow has been deducted from these in each case by a straight line connecting the flow at the beginning and end of the flood period; but no other corrections have been made. The flood of 1927 was caused by a heavy two-day rainfall concentrated in Vermont, with the center of the storm 60 miles up stream from the point of measurement. The 1936 flood flow was due to a storm lasting four days, quite generally spread over the entire area, combined with melting snow. (The bulge on the recession side was due to additional rainfall occurring after the flood peak.) The 1938 flood was caused by five days of rainfall, of which the last two were extremely heavy in the lower part of the drainage area. The center was in Massachusetts immediately down stream from the measuring point. It may be that it is a matter of chance that the distribution and times of these rainfalls were such as to produce these similar hydrographs. However, the writer is inclined to the theory that the storage on a basin integrates storms of different durations and concentrations and tends to produce quite similar hydrographs for similar flow volumes.

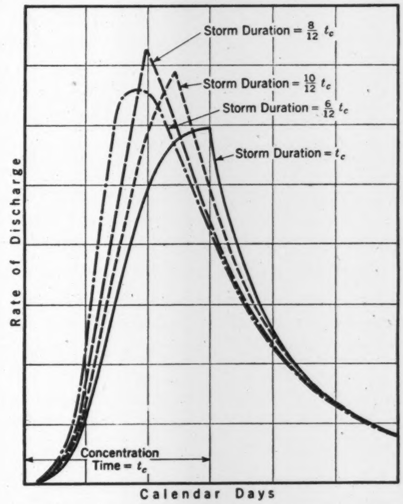

FIG. 17.—"BASIC HYDROGRAPH" AND CORRESPONDING HYDROGRAPHS FOR STORMS OF SHORTER DURATION BUT WITH SAME TOTAL RAINFALL

This is quite at variance with the author's basic hydrograph theory for a similar run-off taking place in 6, 8, 10, or 12 twelfths of the concentration time. Fig. 17 shows the author's hydrographs of floods of varying times taken from his Fig. 2 and multiplied by the proper factor so that each will represent the hydrograph of a flood from storms of the same magnitude but occurring at different times. On this basis the flood produced by a storm of the same size, but in 83% of the time of concentration, will produce a very different shape of hydrograph, with a peak 15% greater. The same storm occurring in 67% of the time will produce a still different hydrograph with a peak 20% higher. This appears to the writer to be a much finer distinction than is found in actual flood hydrographs. He believes that the storage for the entire length of the main river and of its tributaries through the entire system, and the time of travel of the flood into, through, and out from such storage, tend to cause hydrographs of similar shape for flood volumes of the same size, although there may be quite large differences in the length and distribution of the storm rainfall on the drainage area.

The author is in error regarding the history of modern flood hydrograph analysis. It was the report of the Committee on Floods of the Boston Society of Civil Engineers[28] at first revealed the fact that hydrographs from isolated storms had practically the same length of base. It contains the following statement:[28] "the Committee shows that a flood hydrograph once determined for a given river, even for an ordinary flood, will serve as a basis for the estimation of greater flood run-off, due to the fact that the base of the flood hydrograph (or time of flood period) appears to be approximately constant for different floods." On the next page exceptions are pointed out, among them, "the effect of storms which are of longer duration than the concentration period."

If individual recognition is to be given for this it should go mostly to Mr. S. S. Kent, Assistant Engineer of the Proprietors of the Locks and Canals, Lowell, Mass., who was Chairman of the Sub-Committee on "Flood Formulæ for New England" of the Committee on Floods of the Boston Society.

The author further states that the formulas of the Boston Society of Civil Engineers[28] "are based on the assumption that the drainage area involved is rectangular and of uniform slope, like a shingle on a roof, and without any well-defined channels" (see text following Equation (1)). Although it is true that such rectangular drainage areas were used in investigating the effects of different shapes of areas on the hydrograph, the final formula was a general one. The flood coefficients, C_f, were determined and flood hydrographs on a unit basis called "characteristic flood curves" were given for a number of New England rivers. These are quite similar to the distribution graphs of the "unit graph" system developed more than a year later.

OTTO H. MEYER,[29] ASSOC. M. AM. SOC. C. E. (by letter).—The discussions have indicated a gratifying interest in this subject, and have directed attention to the need for further investigation, particularly on infiltration and seepage.

Mr. Cochrane attempts to derive the shape of the falling limb of the hydrograph by an inversion of the rising limb. The writer believes that the discharge, at any time after the time of concentration and after the cessation of the rain, must be determined by a function of outflow from storage. This is sufficiently well established by numerous studies of depletion curves[7, 8], and by the study referred to by Mr. Barnes. The sharp break at the top of the basic hydrograph, questioned by Mr. Cochrane, and also by Messrs. Zoch and Turner, is definitely verified by the hydrograph of Fig. 10 presented by Mr. Sherman. The writer has no criticism to offer on formulas for maximum flood discharge; however, these are outside the scope of this paper.

[28] *Journal*, Boston Soc. of Civ. Engrs., September, 1930, p. 297.

[29] Asst. Engr., U. S. Engr. Dept., U. S. Engr. Office, Sacramento, Calif.

Mr. Barnes makes a timely comment as to the unreliability of the per cent run-off, or run-off factor. This factor is used where nothing better is available. As mentioned by Messrs. Sherman and Zoch, better results will follow from the deduction of infiltration from rainfall, and the consequent use of "net rainfall." However, infiltration and seepage are a separate subject, and consideration of them would complicate the subject unduly without affecting the characteristics being analyzed. In any case, a distribution of precipitation intensity giving a constant "net rainfall" is not impossible and would fit the assumptions on which the analysis was based.

The "subsurface storm flow" or "secondary base flow" mentioned by Mr. Barnes is an item of run-off of sufficient importance to merit considerable study. There can be no doubt that this type of run-off occurs and is often of considerable magnitude. The writer visualizes the source of this run-off as a sheet of water separated from the true "ground-water," possibly by a cushion of air filling the voids of the soil. Presumably, the same methods of analysis used for true surface run-off may be applied to a study of subsurface storm flow; however, it must be treated separately from surface run-off.

Mr. Sherman has apparently misinterpreted the hydrograph of Fig. 3, as no termination is indicated; the tail is intended to be of infinite length, only a portion being shown. As Mr. Sherman states, the use of unit hydrographs in combination, as shown by his example in Table 7 and Fig. 10, is a practical working tool, and the writer also uses this method, where applicable, on account of its simplicity. However, if the unit hydrograph used is that for a storm duration close to, or equal to, the time of concentration, inconsistencies may be expected to develop. For example, with a unit hydrograph for a one-day storm, if the tail is several days long, and the time of concentration is one day, a one-day rain produces a peak equal to the rainfall rate, but a two-day rain must necessarily cause the computed peak to be greater by the amount of the rate of discharge of the tail of the unit hydrograph one day after the peak of the unit hydrograph. This cannot occur in nature. The observed hydrograph of Fig. 10 obviously has the characteristics described in the writer's analysis, the time of concentration being about 25 to 30 min.

Mr. Sherman states that the time of concentration and the distribution for a three-day storm, as given in Appendix III, should be derived from the distribution for a one-day storm. This could be done, or, as in the example, the distribution for a one-day storm could be derived from that of the three-day storm, which in this case is the basic hydrograph, the time of concentration being three days. The process is reversible.

Mr. Zoch's distinction between run-off and rate of run-off, and between run-off and discharge, is commended. The writer does not agree with Mr. Zoch's statements on infiltration and internal drainage; however, that is considered outside the scope of this paper.

The writer cannot agree with Mr. Zoch as to the beginning of the depletion curve. It is true that with storms of short duration the part of the falling limb prior to the time of concentration contains both items of accretion and items of depletion; however, the succeeding portion must be pure depletion.

This has been established empirically, and may be reasoned logically. The contribution to flow from every part of the basin has reached its maximum when the time of concentration is reached, and thus can only diminish. For the same reason, the maximum discharge can never be later than the time of concentration. The transition curve mentioned by Mr. Zoch must lie entirely between the end of the rain and the time of concentration. The "saturation curve" is not a part of the basic hydrograph, as it occurs only if the duration of the rain exceeds the time of concentration. The writer, therefore, adheres to the statement that the basic hydrograph consists of the two parts: (*a*) The concentration curve and (*b*) the storage, or depletion, curve.

Mr. Zoch states that the writer has not mentioned the determination of the time of maximum discharge. This time is indicated by the peaks in Fig. 2 and adequately described in the accompanying text.

Mr. Bernard calls attention to the lack of sufficient and suitable basic data for hydrologic studies. It is this very lack which forces hydrologists to use unsatisfactory expedients such as the run-off factor.

The writer would like to call attention to the fact that the definition of time of concentration appears in the second paragraph of the section on "Analysis of the Hydrograph." The mention of time of concentration in the "Synopsis" is not intended for a definition.

In describing, graphically, the sequence of occurrences on a water-shed during a storm, Mr. Bernard makes use of a method which could well be adopted generally in investigations of physical phenomena. Too often there are only the "rationalists," who go into transports of pure mathematics, and the "empiricists," who generalize from meager data. It is only by visualizing actual physical occurrences that engineers can be sure that their derivations are "on the right track."

Mr. Snyder's conclusion that the time of concentration is not the duration of a unit hydrograph is correct. The synthetic unit graph of Fig. 11 includes subsurface storm flow (secondary base flow), and is not all true surface run-off; the basic hydrograph of true surface run-off would reach a maximum of 6 245 cu ft per sec. A separate hydrograph of subsurface storm flow must be constructed if the writer's methods are used. The relative time to peak of the various hydrographs of Fig. 2, commented upon by Mr. Snyder, are subject to errors in drafting. The 1-hr rain would certainly cause a slightly earlier peak than a 7-hr rain.

The writer concurs thoroughly with Mr. Hoyt in his remarks on the necessity for research on the behavior of melting snow.

Mr. Clark ties flood routing and hydrographic analysis together in an admirable fashion. A complete hydrologic study of a large basin must always involve the construction of hydrographs of head-waters and tributaries and routing the combination. An integration of methods used in these two steps is of real value.

The basic hydrograph used to construct one hydrograph in Fig. 7 was synthesized from the unit hydrograph used for the other; the differences may best be understood from a careful study of the method of construction.

Mr. Clark's question on the apparent lack of effect of storage on the rising limb is best answered thus: The steepening of the slope of the water surface during rising stages opposes and nullifies the storage effect, whereas the flattening of the slope during falling stages increases the storage effect and thus makes storage the dominant factor.

In cautioning against indiscriminate use of the expression for time of travel, Mr. Clark has emphasized an important point. The variation of velocity along a stream has not been given the attention it deserves. No assumptions on this subject should be accepted without a most critical analysis.

The effect of land treatment as described by Mr. Jarvis must be considered in any hydrologic study. The writer has encountered this problem in attempting to estimate run-off from irrigated lands, where the irrigation works cause almost complete retention.

Mr. Turner calls attention to the difference in shape of the writer's hydrographs for storms of the same volume but different intensity, and states that actual hydrographs are more similar. He shows, in Fig. 17, hydrographs resulting from storms of $\frac{6}{12}$, $\frac{8}{12}$, $\frac{10}{12}$, and the entire time of concentration. Actual storms lasting through the time of concentration are rare on large streams, and hydrographs resulting from storms of shorter duration than one-half the time of concentration are much more similar than those shown. The writer is of the opinion that the time of concentration of the Connecticut River at Sunderland, Mass., is about 5 to 6 days. Thus the hydrographs of Fig. 16 are not more similar than might be expected, especially as the shapes were probably determined largely by the precipitation occurring in the one or two maximum days of the storms.

No adverse criticism of the Committee on Floods of the Boston Society of Civil Engineers was intended, as the writer recognizes well the value of its work; it was to indicate the necessity for refinement that the shortcomings of the original formulas were mentioned.

In conclusion, the writer wishes to emphasize that it is the physical significance of the shape of the hydrograph, and not the empirical mathematical equations describing it, that is important.

SPECIFICATION AND DESIGN OF STEEL GUSSET-PLATES

BY T. H. RUST,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. R. H. SHERLOCK, L. E. GRINTER, RUSSELL C. BRINKER, C. W. WIXOM, AND T. H. RUST.

SYNOPSIS

An attempt is made in this paper to supply information about the structural steel plates designed to transfer force from one member to another in a structural steel frame or bridge. The forces enter and emerge from these gusset-plates, often by means of rivets, but sometimes through welds. Since a gusset-plate is a point of discontinuity of stress transfer in a structural steel frame, it is here that failures most often occur.

As early as 1867, J. W. Schwedler noted[2] the unequal distribution of stress among the rivets in a riveted connection. He found that the end rivets took most of the stress and the interior ones least. Likewise, the ends of a welded connection are more highly stressed than the interior.

This inequality of stress transfer into a gusset-plate can be shown by stressing models of the type shown in Fig. 1, which are carved from single pieces of bakelite to simulate gusset-plates. When forces are applied through the legs to the plate, fringed photographs can be made by the aid of photo-elasticity. The photo-elastic fringes are the means of establishing the stress value $(p - q)$, at a particular point, p being one principal stress and q the other principal stress at right angles to it. Although a $(p - q)$-determination is a good indication of the condition of stress in a plate, a $(p + q)$-determination was made for some of the models. The lateral expansion or contraction of the stressed plate at any point is proportional to the $(p + q)$-stress at that point. This change in thickness was measured by a light interferometer. From the $(p - q)$ and the $(p + q)$-stress determinations, the value of the principal stresses, p and q, can be found.

Studies of several different shapes are reported herein and the stresses encountered are discussed. The models were designed with special reference to

gusset-plates. A part of the paper is devoted to recommendations for the design and specification of steel gusset-plates.

TESTS

Tensile forces were applied to the model shown in Fig. 1 by means of steel pins through the bushings. A force enters through the top pin, passes down the upper legs into the plate and is resisted by a reaction passing through the lower legs to the other pin, which is held in a stationary position. As shown in the side view of Fig. 1, the bushings are beveled to keep the force, *P*, on the center line of the model. At all junctions of the legs and the plate small fillets were provided to minimize local stress concentration. The plates were each about 0.2 in. thick, and the legs were attached to the plate for a distance of 0.75 in.

To avoid residual stresses in the edges of the bakelite plate, the models were annealed and polished as rapidly as possible. They were then subjected to forces, *P*, in the path of polarized light (see Fig. 2). A theory is that polarized light has its vibrations restricted to one plane, in contrast with ordinary light, in which light vibrations are said to be in many planes. When a beam of ordinary light is passed through a Nicol prism the light vibrations are held to a single plane, and it is then known as polarized light. If this light beam is passed through a second Nicol prism with its axis at right angles to the first prism, the beam disappears, and the field becomes dark. Since there are no vibrations perpendicular to one plane in a beam of interrupted polarized light, the second prism (termed the "analyzer") cannot transmit any light because its axis is at right angles to the axis of the first Nicol prism or polarizer.

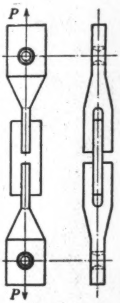

FIG. 1

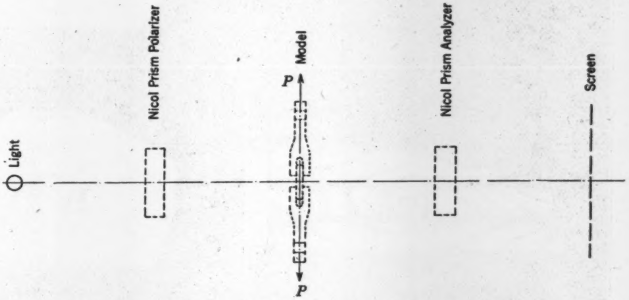

FIG. 2

If a polished bakelite model under stress is placed between the two prisms in the path of the polarized light, the second Nicol prism, or analyzer, transmits light between dark fringes. All the points on a particular dark fringe are of equal $(p - q)$-stress in the plate of a model. Monochromatic mercury light was used.

The change in $(p - q)$-stress from one fringe to another is constant for a given thickness of plate. This stress change between fringes is determined by subjecting a pilot specimen of the bakelite to known loads.

FIG. 3.—FRINGED PHOTOGRAPHS OF PLATES OF DIFFERENT SHAPES

Fig. 3 shows fringed photographs for plates of different shapes. The plates of Models A_1, B_1, and C_1' were $\frac{5}{8}$ in. wide at the mid-length; for Models D_1, D_2, and D_3, the plates were 1.25 in. wide at the mid-length. For Models A_1, B_1, C_1', D_1, D_2, and D_3, the area of the plate at mid-length was nearly equal to the area of the two legs. The closeness of the fringes near the ends of the plates, at the legs, shows the rapid transfer of stress into the plates at those points. The unit stress in the legs is large at this point, whereas in the ends of the plate at the legs the unit stress is small. The difference in the unit stress of the legs and the plate causes rapid stress transfer. At the mid-length of the legs, the bakelite in the legs is stressed to about the same value as the plate. The comparatively great distance between the fringes in the plate at the mid-length of the legs, shows the less rapid transfer of stress at this point, Near the ends of the legs the unit stress is small in the legs; whereas the unit stress and unit deformation in the plates are large. This change in deformation accounts again for a rapid transfer of stress into the plate. The shear stress between the plate and the legs can be represented by a curve shown in Fig. 4. A smooth curve as indicated by the full line would be shown by a welded connection or a continuous connection such as exists in the models. A line of rivets would indicate a stepped curve as shown by the dotted lines in Fig. 4. A rivet or a row of rivets perpendicular to the length of the member would transfer an increment of shear into the plate equal to the area under the corresponding step.

If the cross-sectional area of the legs is equal to the area of the plate, the shear stress transfer at the end of the plate and at the ends of the legs would be of the same value. On the other hand if the area of the legs is less than the area of the plate there will be a greater transfer of stress into the plate at the end of the plate because of its greater stiffness, with correspondingly less transfer of stress at the ends of the legs, as shown in Fig. 5. If the legs were larger in area than the plate, the end ordinates of the curve would be reversed, as shown by the dotted curve.

Boundary Stresses.—At the outside boundary of a plate, symmetrical about the legs (as shown by Models A_1, B_1, and C_1', Fig. 3), the change of stress is less rapid than it is next to the legs. If this were not so, the $(p - q)$-fringes would extend from the sides of the legs, straight across the plate, to the boundary. The extension of the fringes, forward toward the mid-length of the plate, shows how stress lags at the boundaries of the plate. Corners of the plate are points of least accessibility of stress and the positions of zero stress. These corners, therefore, are good places to begin counting the fringes; each succeeding fringe represents a constant increase in $(p - q)$-stress over the preceding fringe.

The boundaries at the mid-length of the plate are the most highly stressed. The stress at that point also lags considerably behind the stress in the center of the plate at the corresponding positions. At the mid-length of the legs in Model A_1, Fig. 3 (which is approximately at the quarter-point of the plate), the fringes are nearly perpendicular to the boundary. There is comparatively little transfer of stress into the plate from the legs at this point, with less disposition of the stress to lag at the boundary. The same boundary stress condition is shown in Model C_1', Fig. 3, at the third fringe from the top, and again less definitely at the third fringe from the bottom. The wide fringe on the wide side of Model C_4' at the position of the upper leg shows that the increase in area of the plate practically compensates for the transfer of stress from the legs, causing little change in $(p - q)$-stress in the plate at this point on the boundary. The third fringe from the top on the narrow side of the plate turns back. This is caused by the bending moment due to the eccentricity of the plate. The bending stress more than compensates for the tendency of the stress to lag at the boundary. The fourth fringe of Model C_4' turns forward again because the more rapid transfer of stress from the legs near the ends causes the boundary stress to lag again. The same phenomena are shown in Models C_5', A_3, and B_5.

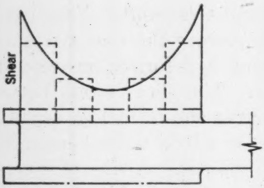

FIG. 4

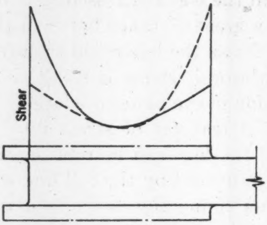

FIG. 5

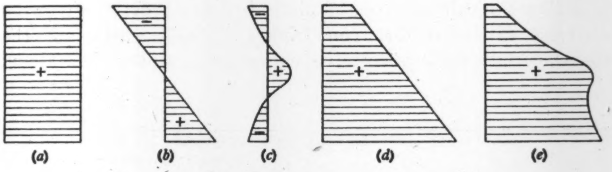
In order to show something about the plate corner effects, the corners on the left side of Model D_1, Fig. 3, were filed off for one-fourth the distance of the leg for Model D_2. There is a more rapid change of boundary $(p - q)$-stress near the left side of the leg in the plate of Model D_1 than in Model D_2. Due to greater resistance to stress transfer in Model D_1 than in Model D_2, the stress builds up more rapidly near the leg in Model D_1 than in Model D_2. The upper left-hand corner of Model D_1 has a larger area free of stress than Model D_2. Model D_1 has less continuity of stress transfer than Model D_2 in the upper left boundary. The $(p - q)$-stress in the right side of the gusset-plate shows almost no change from the removal of the corners on the left side. The upper outside corner of the right side of the plate is at the end of the leg, whereas the lower outside corner is only three-fourths the way along the leg toward its end. The $(p - q)$-fringes do not show any appreciable lack of symmetry due to this difference. The second fringe from the right on the right side of the plate bends out sharply near the boundary. This is true of the second fringe of all the D-models; for Model D_3, Fig. 3, the third fringe also bends out sharply at the boundary. The rapidly increasing area of the plate is more than sufficient to counteract the addition of stress from the legs at these points. It should be noted that the stress transfer from the legs is a minimum near the mid-length of the legs.

Model D_3, Fig. 3, was made by filing concave cuts in Model D_2. In these models there is less unit shear on the right side of the legs near the end of the plate than on the left side of the legs, because there is less material there and, therefore, less resistance. The smaller unit shear causes less shear stress in the end rivets or ends of welds, as well as less bearing stress on the plate from the end rivets. Since the rivets at the end of a gusset-plate as well as their bearing stresses on the gusset-plate are critical, it is well to make the plate comparatively elastic by not having its surface area much larger than the end rivets require.

The vertical boundaries of the plate of the *D*-models are almost free of stress. These boundaries are so far from the direct path of stress transfer that they are not highly stressed, in accordance with the theory of least energy.

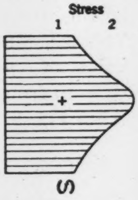
Interior Plate Stresses.—The greatest stresses in the interior of the plate are always between the ends of the legs of the models. All the stress has been transferred into the plate in this region, and it tends to concentrate in the most direct path of transfer. Some of the fringes curve out, which shows the tendency of the $(p - q)$-stress to spread over a larger part of the plate.

The stress condition in a plate may be shown graphically by the diagrams in Fig. 6, that is, Fig. 6(*a*) represents the direct stress on a transverse section assuming uniform distribution; Fig. 6(*b*) represents the bending stress; and, Fig. 6(*c*) represents the stress that minimizes the energy in the plate. The theory of least energy is not satisfied by the assumption of uniform and direct bending



(*a*) (*b*) (*c*) (*d*) (*e*)

FIG. 6



(*f*)

FIG. 7

stress distribution, but requires that the assumption shall be modified by stress similar to that shown in Fig. 6(*c*). Although there is ample evidence in these tests shown graphically by Fig. 7, plotted from readings on the section at the mid-length of the plate of Model A_1 (Fig. 3), there is no generalized theory for the least energy stress condition for Fig. 6(*c*). If the outside forces are applied somewhere near the neutral axis of the plate this added least-energy stress will always have the general shape of the curve in Fig. 6(*c*), the negative area being equal to the positive area (Fig. 6(*d*) = Fig. 6(*a*) + Fig. 6(*b*); and Fig. 6(*e*) = Fig. 6(*a*) + Fig. 6(*b*) + Fig. 6(*c*)); Figs. 6(*d*) and 6(*e*) will have the area of Fig. 6(*a*), because equilibrium of the free body is always maintained between external and internal forces.

In nearly all the models, the fringes that pass near the ends of the legs change curvature. Since the largest concentration of $(p - q)$-stress occurs in the plate between the legs, this stress tends to distribute itself over a greater part of the plate with the resulting change of curvature of these fringes.

With an eccentric plate such as that shown in Model C_5' the fringes denoting the highest $(p - q)$-stress shift over toward the narrower side of the plate. The direct stress, the bending stress due to eccentric loading, and the stress due to the least energy in the plate, create a maximum stress to the right of the center line of the legs. In Model D_3, Fig. 3, there is also a slight shifting of the fringes of highest value to the right of the center line of the legs. On the right side of this model there is less plate in the gusset corners than on the left side of the legs; therefore, the maximum stress shifts again slightly to the right.

In Model C_5' the almost horizontal fringes on the narrow side of the plate show that the bending stress due to eccentric loading is approximately equal to the decrease in least energy stress there. The principal stress, q, is not large except in the mid-length of the plate; even there it is considerably less than the p stress, as will be shown under the heading, "Discussion of Curves."

DISCUSSION OF CURVES

In addition to knowing something of the $(p - q)$-stress distribution from the photo-elastic photographs of the models, it was desirable to know something also about stress distribution in gusset-plates from the plotting of stress curves.

Graphs of $(p - q)$-stress and $(p + q)$-stress along the sides of the legs of Model A_1 are shown in Fig. 8. The $(p - q)$-stress difference between fringes was found by experiment to be $\frac{84.6}{0.183} = 470$ lb per sq in.; 84.6 lb per sq in. would be the stress difference between fringes in case the bakelite were 1 in. thick. This constant divided by the thickness of the plate used in Model A_1 gives the value of $(p - q)$-stress difference between fringes. The positions of the $(p - q)$-fringes together with their successive values were plotted for Model A_1 in Fig. 8.

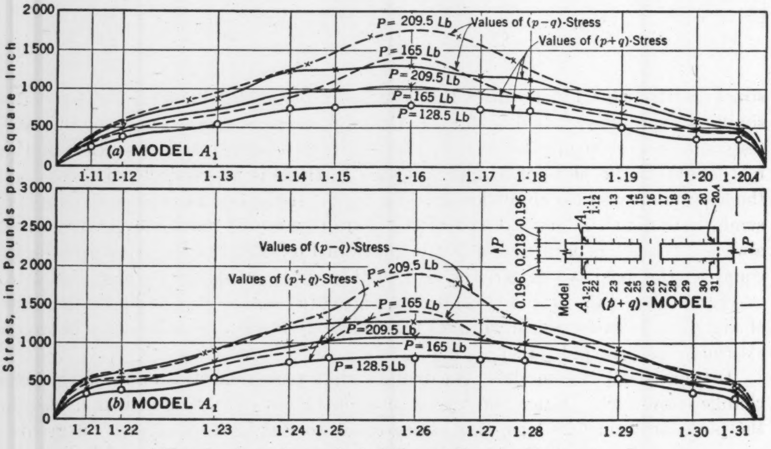


FIG. 8.—$(p - q)$ AND $(p + q)$ STRESS CURVES, MODEL A_1

The $(p + q)$-curves were plotted from values obtained by measuring the lateral contraction of the stressed plates at various points along the legs. The lateral contraction or expansion at a point of the stressed plates is proportional to the $(p + q)$-stress at that point. This lateral change in thickness of the bakelite plate was measured by a light interferometer,[3] and the resulting stresses were plotted as shown. The $(p + q)$-curves and the $(p - q)$-curves nearly agree except at the mid-length of the plate, which indicates that there is little q-stress except at the mid-length of the plate. Since there is a large concentration of stress directly between the ends of the legs, an appreciable q-stress arises in the effort to distribute the stress over a larger part of the plate. The difference in ordinates between the $(p + q)$-stress and the $(p - q)$-stress curves for a particular load, divided by 2, gives the q-stress for a particular point. The addition of the ordinates, divided by 2, gives the p-stress at a particular point.

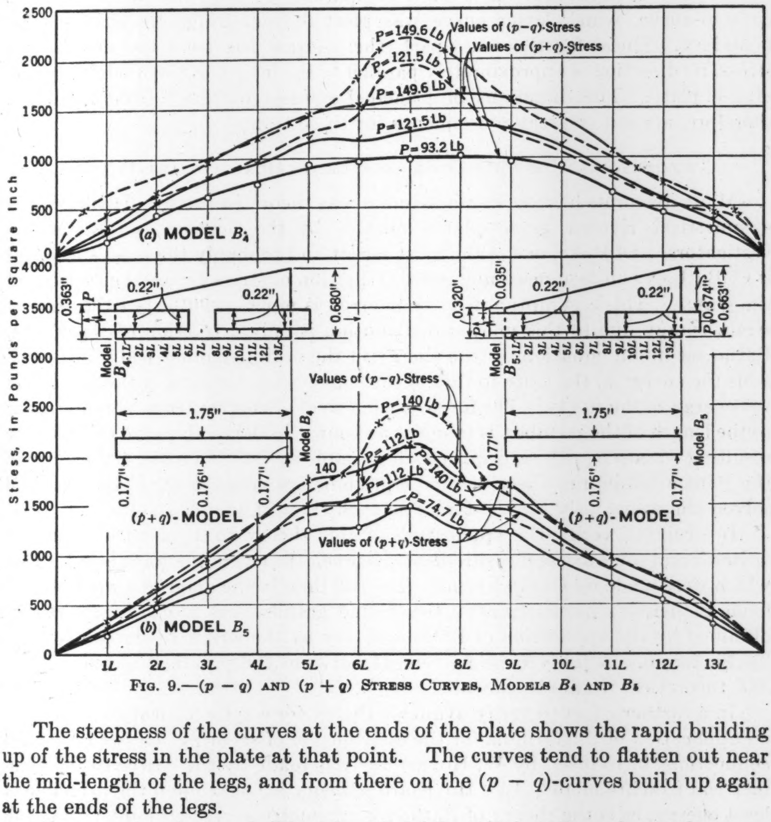

FIG. 9.—$(p - q)$ AND $(p + q)$ STRESS CURVES, MODELS B_4 AND B_5

The steepness of the curves at the ends of the plate shows the rapid building up of the stress in the plate at that point. The curves tend to flatten out near the mid-length of the legs, and from there on the $(p - q)$-curves build up again at the ends of the legs.

The secondary humps in Fig. 9 for Model B_5 at Point $9L$ are due to the stress (particularly the q-stress) tending to distribute itself over a greater part of the plate. There is considerable q principal stress between the ends of the legs in the plate; its tendency to spread over a greater part of the plate depresses the $(p + q)$-curves. No increment of $(p + q)$-stress is added in proceeding from Point $9L$ to Point $8L$ in Model B_5. The same phenomenon of $(p + q)$-stress distribution is shown also between Points $5L$ and $6L$ in the tendency of the $(p + q)$-curves to flatten out.

Sets of curves for $(p - q)$-stress and $(p + q)$-stress were plotted for the outer boundaries, with practical agreement. Since there is only one principal stress along these boundaries—the p-stress—the two corresponding curves for a particular model should agree. It was impossible to place the points of contact of the light interferometer exactly on the boundary. The contact points had to be moved in $\frac{1}{16}$ in. to prevent them from slipping off the model. This accounted for a slight difference in a comparison of a $(p + q)$-curve with a $(p - q)$-curve, which latter curve was plotted from fringe readings on the boundary. Since, for the most part, the p-stress has been the dominating stress, its direction is approximately parallel to the length of the model for most of the plate. The directions of principal stresses obtained from isoclinics, therefore, are not of great consequence for these tests.

THEORETICAL CONSIDERATION OF SYMMETRICAL GUSSET-PLATES

Many attempts have been made to find the theoretical stress distribution in symmetrical, riveted, gusset-plates, notably by the German and British investigators. Of these, one of the most recent and probably the most successful is C. Batho,[4] who assumes a uniform distribution of stress across the sections of the plates. This assumption may be in error as much as 20%, but the error of strain energy due to this uneven distribution is only a fraction of 1 per cent. Batho set up an equation for the energy in the entire symmetrical joint which adds the energy in the plate to that of the connecting members at the plate, and the energy in the rivets. The force on each rivet or row of rivets, perpendicular to the length of the member, is taken as unknown. Derivatives are taken of the resulting equation with respect to each variable force. To make the energy in the joint a minimum, these derived equations are equated equal to zero, and solved simultaneously for the forces at each rivet or row of rivets.

In order to verify the application of this theory to a practical case, the writer found some stress measurements between the rivets of a joint (see Fig. 10) which were made by C. Findeisen.[5] The full lines in the diagrams were plotted from Findeisen's measurements; the dotted graphs were plotted from results obtained by the application of Batho's theory by the writer to the joint tested by Findeisen. A fairly close agreement between the practical measurements and theoretical results is shown.

In a further effort to verify available theory for a symmetrical welded joint, an application of the formula for the distribution of shearing stresses in welded connections introduced by W. Hovgaard,[6] was made by the writer to the symmetrical bakelite model, A_1. Hovgaard's theory is based upon the principle of least energy, as is the theory of Batho for symmetrical riveted joints. Instead of deriving the work equation with respect to each force, X_n, on each row of

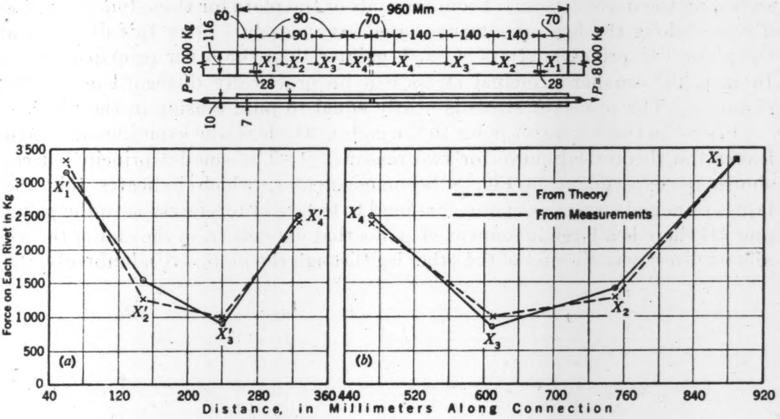

FIG. 10.—BATHO'S THEORY APPLIED TO FINDEISEN'S STRAIN MEASUREMENTS

rivets, and equating the derivatives equal to zero for a solution of least energy as Batho has done, Hovgaard writes an equation for the energy in the connection as a function of the shear stress at any point, X, of a welded connection of the member to the plate. The equation is minimized by variational calculus, and the solution of the differential equation obtained. The constants in the equation can be evaluated for a particular practical problem.

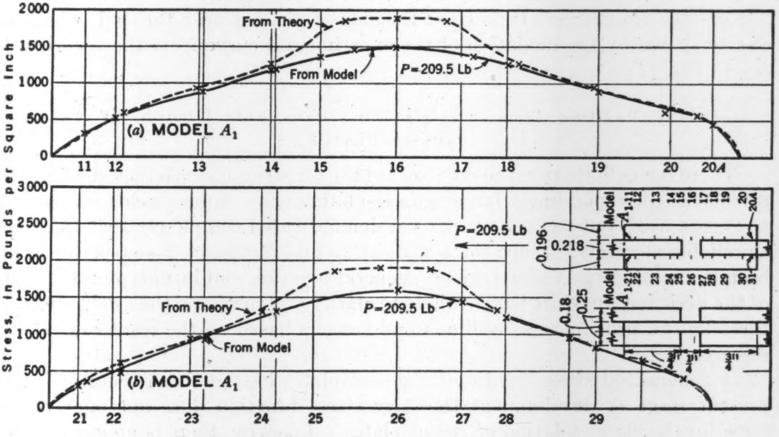

FIG. 11.—HOVGAARD'S THEORY APPLIED TO MODEL A_1

The results of Hovgaard's theory applied to Model A_1 are shown on the plotted graphs of Fig. 11. The full lines show the stresses along the legs in the plate of the model; the stresses from the equation applied to the model are shown by the dotted lines. From the ends of the plate for three-fourths of the distance along the legs, the curves agree very closely. Over this distance in the plate, one principal stress is much greater than the other principal stress. In fact, the smaller principal stress can be practically disregarded for this distance. The resultant stress is nearly equal to pure tension in the plate.

From the three-quarter point to the ends of the legs, the experimental curve leaves the theoretical curve for two reasons: (1) The smaller principal stress shown by experiment in Fig. 8 becomes greater, which indicates that the larger principal stress does not correspond to the exact tensile stress in the plate; and (2) there is a large increment of stress that extends from the end of the leg almost directly to the end of the other leg through the plate. Undoubtedly, the second is the most important reason for the deviation of the experimental curve from the theoretical. Path *b–b–b* shown in Fig. 12 is shorter and more direct than Path *a–a–a*; therefore, a definite increment of stress transfer takes place from the end of one leg directly to the end of the other leg. This increment relieves the transfer of stress from the side of the leg near the end, which is clearly shown by the deviation of the experimental curve from the theoretical one in Fig. 11.

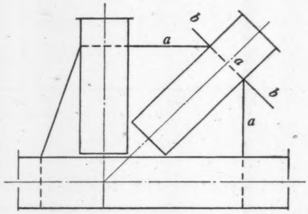

FIG. 13

RECOMMENDATIONS FOR THE SPECIFICATIONS AND DESIGN OF STEEL GUSSET-PLATES

There is a definite trend to-day toward the construction of larger steel structures with correspondingly larger gusset-plates. Sometimes, welds instead of rivets are used, but welds have not yet demonstrated completely that they are as reliable as rivets. Since the specification and design of gusset-plates have been the result largely of experience, general practise, and intuition on the part of the designer, an effort will be made to clarify and to extend the application of these known principles, as well as to add others based on the results of recent research.

A generalized stress solution for gusset-plates has not been found. In its present stage of development the Airy stress function does not offer much hope for the stress solution of gusset-plates. Likewise, there is no generalized stress solution about the phenomena of fatigue. Solutions for stress in symmetrical gusset-plates have been found both for riveted and for welded connections. The solution for symmetrical, riveted gusset-plates was found by Batho[4] whose solution is based on the principle of least energy, as is also that of Hovgaard[6] for symmetrical, riveted, and welded plates. The writer applied Batho's method to Findeisen's strain measurements on a symmetrical riveted plate connection; the writer also applied Hovgaard's method to the symmetrical bakelite model, A_1. The stress observations on bakelite models have been discussed in a previous part of this paper. The discussion will be broadened, however, to include considerations based upon general practice and present manufacturing procedure in order to give a more complete view of the art.

General Practice.—For small structures, gusset-plates can be designed and specified without great difficulty provided there is no reversal of stress. The rivet groups can be made comparatively short in the direction of the length of the member. Since there is less chance for distortion of the material, a shorter group allows a better distribution of stress between rivets. In small structures one or two gusset-plates are commonly used for each joint; but for larger ones, four or even more gusset-plates are necessary. The late J. A. L. Waddell,[7] Hon. M. Am. Soc. C. E., has recommended that there be as few cuts as possible in the plates, and that it is desirable to line up the gussets for appearance. For light gussets not subject to reversal of stress, they may be subordinated, without harm, to the appearance of the trusses and to fabrication economy; but for large and heavy structures the gusset-plates may well influence and even dominate some of the decisions as to the design and fabrication of the truss.

Long and narrow gusset-plates nearly always are computed, by elementary mechanics, more highly stressed than those with approximately equal axes. A long and narrow gusset-plate with diagonal members will have considerable eccentricity about the neutral axis of the gusset at some of its sections. Such connections are usually longer and less desirable than connections of diagonal web members with steeper slopes to the chord members. Long connections have a greater disproportion of stress among the rivets, with more low stressed rivets in the mid-length of the connections. An ideal gusset approaches a circle in shape, or a polygon of approximately equal axes, with all the forces intersecting at or near its center. A gusset-plate of such shape, due to its maximum width at the center, does not have great bending stresses. Furthermore, the longer section at the center allows the principle of least energy at the often critical center section of the gusset to function over a greater distance, with less stress concentration between the ends of the members (see Fig. 3). The shorter and wider rivet groups with respect to the length of the member tend to cover a larger rather than a smaller part of the gusset-plate, which implies that the gusset should be of no greater area than necessary. Gusset-plates with comparatively large unriveted areas increase the discontinuity which the joint represents.

The rivets should be of no greater spacing in a member connection than good design permits because the variation in stress from one rivet to the other will be less for the smaller spacing.

The cross-sectional area of the gusset where the member connects to it should tend to approach the area of the member at that point, and should not be (as is often the case) of much greater area. The plate shown in Fig. 13 should follow a line, *a–a–a*, rather than a line, *b–a–b*. The ideal of uniform stress transfer among the rivets can never be realized. The end rivets will always be the most highly stressed ones, as shown by the graphs of Fig. 10. The rapid building up of the stress in the plate, at the end of the plate, and at the ends of the legs of the models, is shown in Fig. 3. The stress difference between the end rivets and the intermediate ones can be reduced by making the rivet groups as short as practicable.

---

[7] "Bridge Engineering," by J. A. L. Waddell, 1925, pp. 518–525.

Manufacture.—Gusset-plates should be manufactured with great care. This is especially true of the larger and larger gusset-plates that are continually being demanded. They should be made as nearly plane as possible with subsequent care in shipping and handling to insure the plane condition. Plates as thick as 1 in. cannot be placed in close contact even with rivets as large as $1\frac{1}{8}$ in. in diameter. Furthermore, even 0.75-in. plates cannot be fabricated under present practical conditions to insure contact everywhere. Some of the 1-in. plates in experiments reported by J. Montgomerie[8] were subjected to special care in fabrication. Since they were pressed together with high hydraulic pressure, the value of friction which they were able to develop was raised materially. Plates fabricated in the ordinary manner had a resistance to slip of 9 tons per sq in. of rivet area for thicknesses from 0.40 in. to 0.60 in.; 6.6 tons per sq in. for plates 0.75 in. thick; and, 4.3 tons per sq in. for plates 1 in. thick. After subjecting the 1-in. plates to hydraulic pressure and re-riveting them, the resistance to slip was raised from 4.3 to 7 tons per sq in. of rivet area. These experiments show the importance of avoiding the use of plates with contact surfaces that are not planes.

Painted or oiled plates are less resistant to slip than those with no foreign substance added. Better resistance to slip is provided in these cases when the line of stress transfer is perpendicular to the direction of rolling, rather than parallel to it. A well-driven rivet in single shear should provide a resistance to slip of 35% to 40% of the value of the tension in the rivet shank. This tensile value should equal the product of the area of the rivet by the stress of the rivet material at the elastic limit. Rivets driven at the temperature of about cherry red color, with a minimum clearance at the beginning of driving, provide the best resistance to slip. Lower temperatures in driving prevent excessive heating of the plates, which causes brittleness in some carbon steels and more especially in alloy steels. Alloy steels are usually specified with higher unit stresses, and have less resistance to slip than ordinary steels. Large slip resistance takes much load from the rivet hole-wall where fracture often occurs.

Careful fabrication and handling of the parts will add definite strength to the connection. The edges and faces of the plate should be free of notches and scratches where failure can begin. Plates of ordinary thickness, or thinner than 0.75 in., can be sub-punched and reamed, while plates more than 0.75 in. thick should be drilled and reamed. The reamer[9] should be heavy enough and of sufficient velocity to hold it in its true course. All burrs and bits of steel should be removed with care, and the holes at the pre-set end of the rivet should be counter-sunk nearly $\frac{1}{16}$ in., in order to help the flow of the molten metal of the rivet around this shoulder of the hole-wall. In the fabrication of parts, improperly matched holes are not justified.

[8] *Transactions*, Inst. of Naval Archts., Vol. 65 (March 23, 1923), pp. 179–197, London, England.

[9] "Contribution à l'étude expérimental du Rivetage," par Paul Dugué, Bordeaux, France, 1927.

If an important gusset connection can be specified with plates of ordinary thickness and rivets of usual size, it is best to do so. The men who do the mechanical work are able to fabricate the materials of customary size with greater skill and achieve better results. Most of the tools for fabrication of the parts are designed for average steel sections and rivets. If exceptional steel sections and rivets are specified, increments of improvement from skilled craftsmanship may be more difficult if not impossible to obtain.

Stresses.—The stresses in a plate with a re-entrant corner such as Point *A*, Fig. 14, are always greater than the elastic limit even with small forces acting on the gusset.[10] Sufficient material at Point *A* changes into the plastic state to provide a means of stress transfer around the re-entrant corner. If there happens to be reversal of stress, failure occurs at relatively low forces. From the standpoint of excessive stress, gusset-plates with re-entrant cuts should never be specified. If the highly undesirable, and seldom specified, case of a gusset-plate with a re-entrant corner is encountered, a fillet in the plate at the re-entrant corner, with as large a radius as practicable, will facilitate the stress transfer. It is nearly always possible to avoid gusset-plates with re-entrant corners, but the discontinuities in stress transfer at the rivets in gusset-plates cannot be avoided.

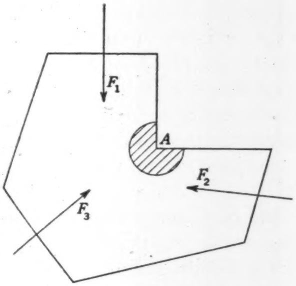

Fig. 14

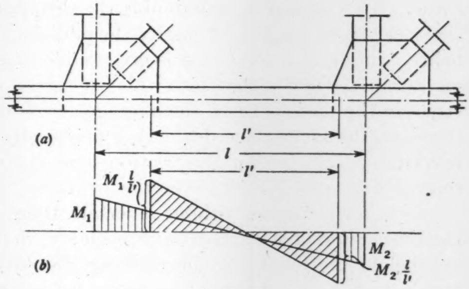

Fig. 15

Since the end rivets of a riveted connection are always the most highly stressed, it is of interest to consider their general method of stress transfer. If the section of the connecting member, carrying pure tension or compression, is equal to the section of the gusset, the percentage of total force taken by the end rivets varies in a manner similar to that shown in Fig. 10. If there are two rivets in a line the end rivets will take 50% of the forces. This percentage decreases to 36.6% for five rivets in a line.[11] From there on, for any addition to the number of rivets, the percentage of total force carried by the end rivet remains at about 36 per cent. Batho's data show that for the case in which the connecting member and the gusset-plate are equal in cross-section area, the end rivets cannot take less than 36% of the force on the member when the stress on them remains within the elastic limit. If there is no reversal, stressing the rivets beyond the elastic limit is of little consequence.

---

[10] "Stress Distribution in a Re-entrant Corner," by J. H. A. Brahtz, A. P. M. 55-6, *Transactions*, A. S. M. E., 1933, Vol. 55, pp. 31–37.

[11] "Riveted and Bolted Connections," by C. Batho, First Rept. of the Steel Structures Research Committee, pp. 100–136.

When reversal occurs, and each stress passes beyond the slip-resistance capacity of the end rivets, the ultimate strength of the connection is greatly reduced. In the design of a riveted connection for reversal of stress, one of the stresses should be kept well within the frictional capacity of the rivets with special reference to the end rivets, to prevent the backward and forward motion in the rivet holes with resultant deterioration of the connection. The cooling of the rivet and the hole-wall after driving causes a lack of tightness, which can never be avoided with heated rivets.

It may be possible to design an important connection with rivets in double shear. This procedure will double the slip capacity of the rivets as well as the shear per rivet, and might justify the additional expense in the shop and in the field. This recommendation is given added weight by the fact that at a point on the surface of the plate into which the stress is transferred in single shear, the stress in the plate is twice the average across the section of the plate, with the stress on the far surface decreasing practically to zero. In order to keep one reversible stress within the friction capacity of the joint, it may be well to re-proportion the joint or even the structure.

Even for members without reversals, there should be as many end rivets in the connection of a member as possible; or, in other words, the number of lines parallel to the length of the member should be a practical maximum. The number of these lines may be increased by welding comparatively long lug angles to the sides of the member, thus adding two or even four lines of rivets to the connection. Since a welded connection is much stiffer than a riveted one, the objection to lug angles is largely overcome. No alternate rivets in the end rows of the connection should be omitted. W. M. Wilson, M. Am. Soc. C. E., with Messrs. J. Mather and C. O. Harris, reports[12] that the section of a tensile connection is not weakened nearly as much by specifying solid end rows of rivets as is generally believed; or, conversely, the section of the member is strengthened only a few per cent by omitting alternate rivets of the end rows.

The decrease in the number of rows shortens the length of the gusset-plate, and thus limits the discontinuity that it represents. Smaller gussets also increase the clear length between joints as shown by Fig. 15(*a*). Moments M_1 and M_2 are from secondary effects. When l' becomes greater Moments M_1 and M_2 become less as a result of the greater slenderness ratio of the member. A. Ostenfeld[13] states that the moments in the members at the gussets as shown in Fig. 15(*b*) have been increased in the ratio, $\frac{l}{l'}$, over what they would have been if the member had been free to bend through the entire distance, l. This factor, $\frac{l}{l'}$, is sometimes termed the gusset factor. In so far as the secondary stresses in a member are concerned, it is important to keep this factor as near unity as possible. From research by K. Havemann[14] the length, l', was found to extend somewhat into the gusset-plates, and he gives the formulas (see Fig. 16):

$$y = a\,c^{x} \qquad (1)$$

and,

$$\log c = \frac{I_M}{I_G}\left[\frac{1}{K}\left(\frac{I_G}{I_M}\right)^{K} - K\right] \qquad (2)$$

in which $K = \frac{a}{l'}$; a = distance from the old origin to the new X-axis, or the distance from the intersection of members to the end of the gusset; y = y-ordinate from the new X-axis, or the distance into the gusset from its end for l';

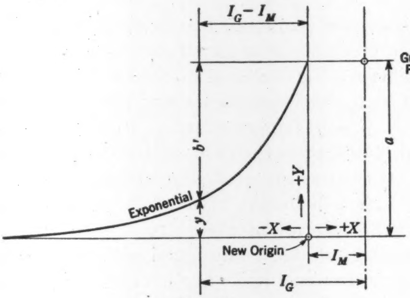

FIG. 16

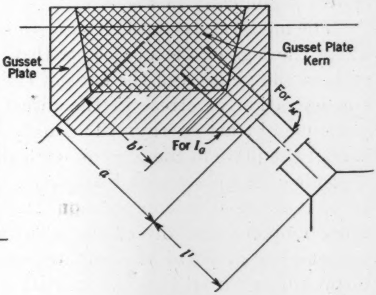

FIG. 17

I_G = effective moment of inertia of the gusset-plate; I_M = moment of inertia of the member; and, $b' = a - y$. The end of the gusset denotes the end of the welds or the end row of rivets. Fig. 17 shows a gusset connection with distances, a, b', and l' of Havemann's formula.

Smaller gussets and lighter sections in the members of the trusses resulted from the multiplication of trusses in the bascule span of the Link Bridge recently completed on the Outer Drive in Chicago, Ill. The greater number of trusses with smaller gussets brought about greater lengths, l', between the gussets for secondary bending in the members (see Fig. 15). The lighter sections also increased the $\frac{l}{r}$ ratios of the members, with a corresponding decrease in secondary bending of the members at the gussets. The smaller gussets in area and section with their smaller rivet groups are better in this bridge than the larger gussets of heavier, fewer trusses would have been.

The secondary moments in the members at the gusset-plates are usually not large enough to be of great importance in the gusset-plate stresses, but with the shortening of the rivet groups the stresses in the end rivets due to these moments should be investigated. The shorter lever arms of the end rivets about the center of gravity of a shorter rivet group increase the load on the end rivets for a given moment. These end rivets are already the most highly loaded ones from the direct stress in the member. On a section of the plate that does not cut any of the members, the bending stress can be found roughly by the usual theory of flexure. This case is seldom met in practice, and may not occur at the critical section. Many gussets have been designed by cutting sections and examining the direct stress, moment, and shear, considering the rivets as uniformly stressed. The bending moment by this method is found by multiplying the forces of the members by their distances from the neutral axis of the section. This moment, divided by the section modulus of the plate at the section, and multiplied by the secant[2] of the angle made by the edge of the plate with the normal to the section, gives an estimation of the stress from bending, at the edge of the plate.[15] This procedure does not consider the non-uniform stresses in the rivets of connections as shown in Fig. 10, or the minimizing stress function shown graphically in Fig. 6(*c*).

---

[14] "Beitrag zur Untersuchung ebener Fachwerke mit steifen Knotenpunkt Verbindungen," von K. Havemann, Darmstadt, 1928.

The model stress data all show the non-uniform stress transfer into the plates along the legs of the models, with the greatest shearing stress transfer at the ends of the plates and the ends of the legs. Fig. 3 also shows the tendency for concentration of stress in the direct path between the model legs from the principle of least energy. The highest $(p - q)$-fringes shift toward the narrow side of the plate in the unsymmetrical plates, or in the case of Model D_3 toward the side of the plate with least area. If the unsupported edge of a steel gusset-plate is stressed in compression, the edge will buckle before failure, throwing more moment and direct stress into the interior of the plate. Parts of the gusset-plate in direct line between members should be designed with the object of providing for all these additional stress increments. The connections of the members to the plate should be made wide, with as many lines of rivets for a riveted connection as practicable.

ACKNOWLEDGMENT

The work[16] reported herein was made possible by the varied facilities at the University of Michigan. The writer is especially indebted to Robert H. Sherlock, M. Am. Soc. C. E., for encouragement and assistance in this research. All the tests took place at the University of Michigan except those of Model *D*, which were made at the Armour Institute of Technology, Chicago, Ill.

---

[15] "Bridge Engineering," by J. A. L. Waddell, 1925, pp. 519–529.

[16] This paper is a part of a thesis submitted by the writer for a D.Sc. degree at the Univ. of Michigan. A complete copy of the thesis has been filed for reference in Engineering Societies Library, 29 West 39th Street, New York, N. Y.

DISCUSSION

R. H. Sherlock,[17] M. Am. Soc. C. E. (by letter).—The gusset-plate is one of the most common details in fabricated steel structures. The intensity and distribution of the stresses in the plates are seldom given any consideration since experience has shown that in ordinary cases a plate will not fail if it is big enough to contain the required number of rivets and has such a shape that it can be cut and fabricated economically. Unusual plates are sometimes analyzed according to the elementary principles of mechanics, one standard specification requiring that "The gusset plates shall be of ample thickness to resist shear, direct stress, flexure, etc."

There is relatively little published material, either theoretical or experimental, dealing with the stress distribution in gusset-plates, so that the engineer finds little to support his judgment in the design of joints lying well outside of previous experience. The stress trajectories in a plate have been found by the mathematical theory of elasticity for only two boundary conditions. In both cases, the load is applied through a single rivet—in the one case to a plate of infinite extent, and in the other case to one-half of an infinite plate bounded by a straight line passing through the rivet. The laboratory research worker knows in advance that there will be little if any opportunity to embellish his report with an elegant comparison between his test results and the results of rational analysis. Progress in this field then must consist in the accumulation of experimental results from a large variety of plate shapes and conditions of loading, thus extending the basis upon which the engineer may exercise his judgment in design.

The author has added to the knowledge in this field through the careful refinement and application of some of the newer laboratory techniques, and through a discussion of present practice in the light of his own results and those of other investigators. It is hoped that the same technique may be applied to more complicated shapes of plates and conditions of loading.

An interesting feature of the photographs in Fig. 3, not referred to by the author, appears in Models B_1, B_5, C_4' and C_5'. Here, the fringes, caused by the light passing through the members attached to the gusset-plates, are inclined to the axis of the members, thus indicating a non-uniform distribution of the stress on the cross-sections of the members. This is in sharp contrast to the fringes in the symmetrical Model C_1' where the fringes indicate a uniform distribution of stress across the members. This indicates again that, if the same welding or riveting is supplied on both sides of the member, the greater stress will occur in the welds attached to the side having the larger area of gusset-plate. All of this is merely another way of showing that the flow of stress is along the path of greatest rigidity.

L. E. Grinter,[18] M. Am. Soc. C. E. (by letter).—It seems strange at first thought that so much attention has been paid to the design of truss members for direct stresses and secondary stresses, whereas relatively little attention has been given to the analysis or design of gusset-plates. The explanation, of course, is that stress analysis of a gusset-plate is a complex process dependent upon the mathematical theory of elasticity, and, as the author has stated, only the simpler kinds of gussets have been subject to analysis at all. It is commendable, therefore, that Mr. Rust has found a device for representing, with reasonable assurance, the relative stress patterns in joints of various shapes and sizes. The meticulous care with which the author has prepared his models, which was observed by the writer, leads to more than usual confidence in the usefulness of the results. His use of the light interferometer for determining the sum of the principal stresses is highly commendable.

[17] Prof. of Civ. Eng., Univ. of Michigan, Ann Arbor, Mich.

[18] Vice-Pres. and Dean, Graduate Div., Armour Inst. of Technology, Chicago, Ill.

One feature of gusset design that seems to be neglected more often than it is considered is the simple one of flexure. There is nothing new about the requirement that the gussets of Fig. 18 must be designed for a combination of direct stress and flexure, but it is often misunderstood. Since the total stress, S_1, must be transferred across the broken lower chord member by the gusset-plate, it is evident that there is flexure to be resisted along Section a-a. The flexural moment is,

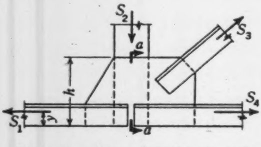

FIG. 18.—ECCENTRICITY AND GUSSET FLEXURE

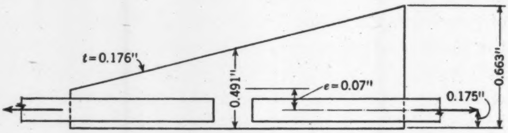

FIG. 19.—ECCENTRICITY OF MODEL B_4

$$M = S_1\left(\frac{h}{2} - y\right) \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Then the total fiber stress may be estimated as,

$$f = \frac{S_1}{h\,t} + S_1\left(\frac{h}{2} - y\right)\frac{6}{t\,h^2} \quad\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

in which t is the gusset thickness resisting the forces shown in Fig. 18. This type of design, in which the gusset is made to serve the function of a splice plate, is not recommended in any specification but it is still used.

It is possible to check this simple analysis against the results obtained by the author for two unsymmetrical models in Fig. 9. Consider Model B_5 for a load of 140 lb. The value of $p - q$ at Point 7L, which is the mid-point, is 2 450 lb per sq in. The corresponding value of $p + q$ is 2 150. The value of p, therefore, is the average of these, or 2 300 lb per sq in. This stress can be recomputed by Equations (3) and (4): $M = 140 \times 0.07 = 9.8$ in-lb; and, $f = \dfrac{140}{0.491 \times 0.176} + \dfrac{9.8 \times 6}{0.176 \times 0.491^2} = 3\,000$ lb per sq in. Thus, for this case, the approximate analysis given by Equations (3) and (4) proves to be safe since it over-estimates the maximum plate stress by 30 per cent. In Model B_4, at a load of 149.6 lb, the actual observed stress is 1 950 lb per sq in. and the fiber stress from Equation (4) is 2 360 lb per sq in., an excess of 20 per cent. The eccentricity is considerably less important for this model than for the one studied first.

RUSSELL C. BRINKER,[19] JUN. AM. SOC. C. E. (by letter).—Technical literature on the design of steel gusset-plates is much too scarce, and therefore Mr. Rust's paper is a welcome one. Rule-of-thumb design has doubtless been practised more on this "detail" than on any other unit in modern steel bridges. Nevertheless, safe designs (although perhaps often uneconomical) have resulted, and the following statement in the "Synopsis" might well be challenged: "Since a gusset-plate is a point of discontinuity of stress transfer in a structural steel frame, it is here that failures most often occur." Unquestionably gusset-plates are points of discontinuity and, therefore, are danger spots, but search of technical literature will disclose few if any instances of major (or minor) failures caused by faulty gusset-plate design. Perhaps that is merely an indication that rule-of-thumb design has been so overly cautious that even in otherwise faulty designs the gusset-plates have been too generously proportioned to permit failure, but it does prompt the statement that, practically, gusset-plates do not fail.

It might be noted that in general, gusset-plate design is based upon two conditions: (1) Selecting a size of plate such that the bearing value of a rivet upon the plate will approximately equal the double shearing value; and (2) providing sufficient area along any section of the gusset-plate to take the stress upon that section (brought by the rivets). As for condition (2), for specifications allowing 24 000 lb per sq in. in bearing and 12 000 lb per sq in. for shear, an $\frac{11}{16}$-in. plate will give balanced rivet values. For most modern spans, gusset-plates are usually made $\frac{5}{8}$ in. thick, or slightly less than the thickness required for balanced rivet values.

A point that has been neglected—apparently without serious results—is the possibility of buckling of the plate. In rare cases, stiffening angles or "flats" may be riveted along the edges of the plate to prevent the occurrence of such failures. The fact that a reduction in thickness requires more rivets, with a consequent enlargement of the plate, has tended to keep the plates heavy enough to prevent failure.

An important series of investigations performed to determine desirable sizes and shapes of gusset plates has been discussed by Theophil Wyss.[20] Two points worthy of note in his results were: (1) The maximum angle over which the stress spreads from the member through the gusset-plate is about 30°; and (2) an analysis can be made of the condition by which gusset-plates receive direct stress and also a twisting moment, in the same manner that a beam is designed for direct and bending stress by means of the formula,

$$f = \frac{P}{A} \pm \frac{Mc}{I} \quad \text{.......................} \quad (5)$$

[20] "Forschungsarbeiten Auf Dem Gebietes Des Ingenieurwesens," by Theophil Wyss.

C. W. Wixom,[21] Assoc. M. Am. Soc. C. E. (by letter).—A subject on which little information has been available is presented in this paper. Mr. Rust recommends that the non-uniformity of stress among rivets be minimized by making the groups short and compact without elaborate attempts to increase net sections. This recommendation has been strikingly supported in the paper entitled "Tension Tests of Large Riveted Joints."[22] These latter tests, however, led to the further conclusion that the present practice of assuming equal rivet stresses is satisfactory. Consistently, this assumption should be made not only in determining the number of rivets but when investigating gusset-plate stresses.

Tests and analyses of splices in which the stresses are principally direct and central, although valuable in themselves, are of limited application in analyzing gusset-plates in which stresses are transferred principally by shear and flexure. However, in the case where a gusset forms part of a chord splice, there is a large direct stress and also considerable bending stress in the gusset due to the location of the chord near the edge of the gusset. It is sometimes desirable to separate the splice from the gusset and eliminate this source of bending.

The statement that "An ideal gusset approaches a circle in shape, or a polygon of approximately equal axes, with all the forces intersecting at or near its center" will not be accepted by all (see heading "Recommendations for the Specifications and Design of Steel Gusset-Plates: General Practice"). The usual gusset connects one or two diagonals (Fig. 20 or 21), a vertical, and a chord. The "ideal" shape of such a gusset just encloses the rivet groups and is rectangular. The point at which the forces intersect is seldom near the center of the gusset. The gusset in Fig. 13 has been superimposed in dashed lines for comparison on Fig. 20. The entire stress from the vertical is transferred as a shear between the vertical and the diagonal. An extension of the gusset to the left of the vertical is of no assistance in this shear transfer. An experienced detailer can frequently lay out an efficient gusset with a rectangular corner at the diagonal. The stress in the corner rivets will compare favorably with the others because the plate is converging with the number

[22] "Tension Tests of Large Riveted Joints," by Raymond E. Davis, and Glenn B. Woodruff, Members, Am. Soc. C. E., and Harmer E. Davis, Assoc. M. Am. Soc. C. E. (see this volume of *Transactions*).

of rivets.[23, 24] Lug angles, or clip angles, have been shown to be flexible and inefficient.[25, 26] They add to the complexity of the stress path.

Since the lines of force intersect at a point, difficulty is sometimes experienced in visualizing bending in gussets. Perhaps the simplest illustration is that of section "$X-X$," Fig. 20, on which there is a bending moment equal to the increment of chord stress times its lever arm "y." The author has quoted the method of analyzing more complex sections.[15]

Gusset-plates should be designed with adequate proportions without undue concern, except in extreme cases, about fabricating limitations or secondary stresses. Many large gussets have been carefully and successfully fabricated for modern structures. Secondary stresses resulting from truss rigidity may be eliminated to a large degree by proper cambering—that is, by fabricating with lengths of members, but not the angles between the members, corrected for their deformation under dead load plus a percentage of live load. In this manner, reverse secondary stresses are induced during erection and these are relieved when the loads are applied.

Of two structures designed for the same duty, the one having the fewer members will often be the more economical—not only in first cost but in maintenance. It will be easier to paint. Since its members and gussets are larger, it will vibrate less and develop fewer loose rivets. Painting of contact surfaces not only reduces the friction but results in loose rivets.[27] It is now prohibited in the leading specifications.[28, 29, 30]

T. H. Rust,[31] Assoc. M. Am. Soc. C. E. (by letter).—The discussions on this paper have further integrated the subject. Professor Sherlock and Dean Grinter note the difficulty of the mathematical approach to the accurate stress analysis in steel gusset-plates, and Professor Sherlock states the meager achievements in accurate stress determination of gusset-plates.

The difficulty arises when an attempt is made to state, mathematically, the principle of least energy for a plate with finite boundaries. The forces concerned are those parallel to the plate, applied at points within the plate rather than those applied perpendicular to it. The stress will flow from one force to another along many paths. The amount of stress along a particular path will be a function of its length and the rigidity of the material. Stored energy is a product of force by displacement, or a summation of such products; and the stress in the plate will distribute itself along the various paths in such a manner as to make the total energy in the plate a minimum. A prismatic plate with

two opposite forces applied uniformly over its ends will be uniformly stressed similar to Fig. 6(*a*). However, if the forces are applied at points in the ends of the plate, and if the plate is other than narrow in an engineering sense, another component of stress will be introduced from the principle of least energy as shown by Fig. 6(*c*). If there is little bending stress, greater stress will lie in the path directly between the two forces than in any other longer path through the plate. It is this variation of path in stress transfer in gusset-plates from one attached member to another which makes the accurate determination of stress so difficult.

Dean Grinter's calculations of stress in the bakelite models reveal similar difficulties. In Models B_4 and B_5 the computed maximum stress at the edges is less than that given by the formula for direct and bending stress. This is because the path in the plate between the ends of the legs is the most direct one and hence takes more least energy stress than the longer paths at the edges. The wider plates of the *D* models show this phenomenon to an even greater degree, the stress at the edges being almost zero. It is well to note that the behavior of stress in bakelite models simulates that of steel in a qualitative, rather than in a quantitative, manner. The fringes fall off more rapidly in the bakelite than they would in a steel plate because the modulus of elasticity of bakelite is only about 550 000 lb per sq in. in comparison with 29 000 000 lb per sq in. for steel. As an extreme example of the localization of stress due to the elasticity of the material, a pin thrust through a thin sheet of rubber could be moved back and forth laterally in the plane of the sheet, producing only local distortions, and points at some distance would suffer little or no distortion. Steel models would not have this quantitative handicap, since all three types of stress (*a*), (*b*), and (*c*), shown in Fig. 6, would appear in their true values if the proper scale relations were maintained between model and prototype. After they are in the plate, the $\frac{P}{A}$-values and the $\frac{Mc}{I}$-values are independent of the modulus of elasticity of the plate, provided the material satisfies Hooke's law in the region considered. It is only the "minimizing stress" (Fig. 6(*c*)) that is thus affected. Photo-elastic methods could not be used with steel models; but perhaps other methods could be employed such as covering the plates with a thin layer of material which would show changes after the steel plates were subjected to stress.

In the absence of well validated methods for obtaining quantitative information, the qualitative knowledge is a definite help to the careful designer.

Although the mathematical methods are intricate and not far advanced for the study of stress in plates of finite boundaries, with forces applied at points within the boundaries and parallel to the planes of these plates, still progress might be made by methods analogous to those developed by the German physicist, Walter Ritz.[32] He made some noteworthy solutions in thin plates of finite boundaries, with forces applied perpendicular to the planes of the plates, by using variational calculus, polynomials, Green's theorem, and Fourier series. The continual refinement of results by Fourier series parallels the designer's successive approximations in his calculations and designs.

Professor Brinker states that search of the technical literature will disclose few if any instances of failures caused by faulty gusset-plate design. It is indeed unfortunate that more structural failures are not described in the literature, since the primary cause of failure is not always disclosed by a casual inspection afterward. The close study that accompanies the preparation of an engineering analysis and report might very well have placed the blame on these points of discontinuity. Engineers agree quite generally that failures are in the joints and details rather than in the bodies of the members.

Professor Brinker also notes that the gusset-plate should not have an angle of less than 30° with the connecting member. Because of the considerable research that has been completed in riveted joints, gusset-plates, and thin plates,[12, 22] the writer did not include this empirical specification in the paper or in the thesis[16] of which the paper is a part, because of the expectation that it would soon be superseded.

Such matters as thickness of gusset, and reinforcement of gusset to prevent buckling, which Professor Brinker raises should be the result of the specifications and requirements of a particular structure.

Equation (5) has been given in more generalized form, including examples of its application by the late J. A. L. Waddell, Hon. M. Am. Soc. C. E.[15] This formula is approximate and gives only the order of magnitude of plate stresses rather than accurate values.

Mr. Wixom's statement in the first paragraph of his discussion quite agrees with the statement of the writer (see "Recommendations for the Specifications and Design of Steel Gusset-Plates: Stresses"), "If there is no reversal, stressing the rivets beyond the elastic limit is of little consequence." It is this favorable quality in the plastic region of steel that has permitted the specification of gusset-plates to lag in progress behind the specification of members. However, when reversed stresses occur and each reversal goes beyond the slip-resisting capacity of the rivets, the connection is very likely to deteriorate.

It seems that it would be desirable in almost every instance to splice all members outside of the gusset connection and thereby avoid superimposing the discontinuity of the splice upon that of the gusset.

The writer agrees with Mr. Wixom that it would be folly to specify a gusset of approximately equal axes at the expense of long rivet connections or unriveted areas of plate, and the writer regrets that such an interpretation has been placed by Mr. Wixom upon the ideal. The ideal gusset-plate is similar to the ideal engineering structure; it can almost never be realized. However, the writer has found, after the examination of many gussets, with the experience and the elementary theory at his disposal before this research was undertaken, that gussets of approximately equal principal axes with forces intersecting near the center practically never showed high stresses due to bending and direct stress. The desirability of avoiding long and narrow gusset-plates has been reported by Clifford E. Paine,[33] M. Am. Soc. C. E.

Mr. Wixom's objection to lug angles is based upon three considerations: (1) Short lug angles induce moment in the transfer of stress; (2) the added rivet connection causes distortion with resultant stress in the lug angle before it can transfer any stress from the member into the plate; and (3) the added material in the lug angle must be distorted with resultant stress before it can transfer stress into the plate. The first consideration can be minimized by long lug angles. The second, which is undoubtedly the most important factor, can be reduced by welding the lug angles to the members. Welded connections are much stiffer than riveted ones[34]; so the less capacity for transmission of stress due to the added riveted connection can be largely counteracted by welding the lug angle to the connecting member. The entire connection from the member and auxiliaries to the gusset-plate, itself, should be either all riveted or all welded. The third factor can be minimized by making the lug angles as narrow as practicable and of comparatively thick material. This factor is not as important as the first and second factors. For these reasons it does not seem justifiable to condemn all use of lug angles.

In answer to Mr. Wixom's preference for heavy trusses, it seems that best results can be obtained by not attempting to exceed, or even equal, the maximum sizes of rivets, heavy plates, and sections in use at this time. At least, this should apply to important gusset-plates and their connections. Many specifications limit the thickness of plates, eye-bars, and other sections for steel structures, and C. F. Goodrich,[35] M. Am. Soc. C. E., reports that "the limit has about been reached in human strength to handle heavier, high-pressure, rivet guns."

In reply to Mr. Wixom's criticism that the models did not simulate closely enough the complex gusset-plates in actual trusses, it may be said that progress in any laboratory work results from simple beginnings. Also the development of a proper testing technique was of major importance in this research. It is true that the stresses are principally direct in most of the models, and in others the bending results entirely from the eccentricity of the direct load, whereas in actual trusses the presence of diagonals and verticals renders the conditions, more complex. Nevertheless, it is believed that the lessons from these simple models have supplied information for the estimation of stress in more complicated joints; and it is hoped that more involved joints will be investigated in the laboratory.

GREAT LAKES TRANSPORTATION

By M. C. Tyler,[1] M. Am. Soc. C. E.

With Discussion by Messrs. T. Kennard Thomson, Harland C. Woods, W. L. R. Haines, and L. C. Sabin.

Synopsis

The Great Lakes and their connecting channels are of great importance in the national economy and the national defense. The steel industry of the United States was largely built up around lake transportation, and the Great Lakes also afford low-cost transportation for grain and coal. This paper is an attempt to outline the history and effects of lake transportation, the works built during a century for the benefit of navigation, and to describe the existing commerce and shipping. The combined Lake and rail movement of bulk commodities is shown to be efficient and economical. The system has been developed gradually through the co-operative effort of the Government, the railroads, industry, States, municipalities, and the owners and operators of vessels. It demonstrates that good engineering practice and sound business judgment, applied to plans laid down only so far ahead as definite benefits can be foreseen, can produce remarkable results.

Historical

Water transportation on the Great Lakes and on the St. Lawrence River and its tributaries has had a tremendous influence on both the political and economic history of the United States and Canada. The first English colonies were established on the Atlantic seaboard in Massachusetts and Virginia at about the same time that Champlain set up his stockade at Quebec in 1608; so the English and the French got practically an even start at conquering the American wilderness. However, water transportation by way of the St. Lawrence River, the Great Lakes, and by the Ohio, Illinois, Fox, and Mississippi Rivers (see Fig. 1), gave the French explorers, missionaries, and traders a great advantage in freedom and rapidity of movement. By 1755, when the English felt strong enough to attempt to push their claims over the Alleghenies and establish themselves in the Ohio Valley, the French, due to water travel and trade, had

---

swung around in front and far ahead of them, and had built missions, forts, and trading posts at Sault Ste. Marie, Mackinac, Green Bay, Niagara, on the Ohio, Illinois, and Mississippi Rivers, and at Ticonderoga and Crown Point, on Lake Champlain. The British had only one post on the Great Lakes, a small one at Oswego on Lake Ontario. When General Edward Braddock made his futile attempt in 1755 to capture Fort Duquesne, a body of French and Wisconsin Indians was in the battle that resulted in his disastrous defeat. The British, moving overland through a wilderness, could make no headway against the French, who were able to concentrate quickly by water at any threatened point. Only when General James Wolfe cut the root of the French water-transportation system by the capture of Quebec in 1759, and Baron Jeffry Amherst, making use of water transportation, proceeded from Oswego with 10 000 men and 1 300 Indians in hundreds of bateaux and captured Montreal, in 1760, did the far-flung French Empire in America collapse, and then New France became British territory.

During the American Revolution, water transportation available to the British from Quebec and Montreal, nearly brought disaster to the Colonial Revolutionary cause. General John Burgoyne reached Saratoga by means of water transport and Sir John Johnson with his Tories and Indians, from Fort Niagara as a water base, raided the settlements in New York and Pennsylvania along the Mohawk and the Susquehanna Rivers. Even after the treaty of peace, water transportation enabled the British to hold the forts on the American side of the Lakes for a number of years in violation of its terms.

Again, in 1813, water transportation on the Lakes played a decisive rôle. The British, with their Indian allies, captured Detroit and Mackinac, and kept General William Henry Harrison's army ineffective on the Maumee River through the command of Lake Erie by a small British squadron which kept Commodore Oliver Hazard Perry's war vessels blockaded in Erie Harbor. It looked as if the United States might lose all of its Northwest Country. For some unknown reason, the British squadron left its station in front of Erie long enough for Commodore Perry, unmolested, to work his vessels across the bar, on which there was about 5 ft of water. The victory over the British squadron at Put-in-Bay followed; the United States regained the advantages of water transportation for movement and supply; and Commodore Perry, using his own and the captured vessels, ferried General Harrison's troops to the Canadian side. Detroit was re-occupied and the British and Indians were defeated in the Battle of the Thames. Had not the control of the Lakes been retaken, it is quite probable that the great iron ore deposits of this country might now be in Canada.

Steamboat navigation began on the Great Lakes in 1816, with a steamer running between Ogdensburg, N. Y., and Lewiston, N. Y., on the Niagara River. The first steamboat on Lake Erie was put in operation in 1818. The opening of the Erie Canal between the Hudson River and Buffalo, N. Y., in 1825 and the Oswego Branch to Lake Ontario in 1828, and, the completion of the first Welland Canal connecting Lake Erie and Lake Ontario around Niagara Falls, in 1829, expedited the settlement of Michigan, Wisconsin, and Northern Illinois. By 1830, a daily boat line was running between Buffalo and Detroit.

FIG. 1.

The population of Michigan, which was only 4 762 in 1810, reached 212 000 in 1840; and Michigan was admitted as a State in 1837.

From 1835 to 1845, settlers from the Eastern States poured into the southeastern part of Wisconsin, founding Milwaukee and other cities along the western shore of Lake Michigan, with the result that Wisconsin was admitted to the Union in 1848. In 1833, Chicago, Ill., received its first charter as a city and a port of entry, and in 1840 had a population of about 4 500.

Naturally, the early commerce on the Lakes was in grain from the newly broken prairies, lumber from the virgin forests to Eastern markets, and in manufactured goods destined to the West. The first bulk cargo of grain was shipped from Chicago to Buffalo in 1839—about 1 600 bushels of wheat. Five days were consumed in getting the cargo aboard, fourteen days in making the run to Buffalo, and seven days in discharging the cargo. In 1840, Chicago shipped six cargoes of wheat, aggregating 10 000 bushels, and during that year a grain elevator was built and equipped with steam elevating machinery.

The original forest of white pine mixed with red or Norway pine stretched across Michigan, Northern Wisconsin, and Eastern Minnesota. As early as 1850 the lumbering operations in Michigan were extensive. It is stated that there were 61 saw-mills in operation in the State in 1854. By 1890, Michigan, Wisconsin, and Minnesota were cutting more than one-third of all the timber harvested in the United States. This timber supplied the Eastern market and built the towns and farm buildings throughout the Middle West and the Northwest.

Buffalo, with its strategic location at the eastern end of Lake Erie and the western terminus of the Erie Canal, naturally became the principal receiving port and milling point for grain, and Tonawanda, N. Y., the market for lumber, destined for Eastern consumption and for export. Likewise, Chicago and other Lower Lake Michigan ports received great quantities of lumber for distribution through the Middle West.

The earliest explorers had known of the presence of large deposits of virgin copper in the Lake Superior region. It is stated that Benjamin Franklin, when negotiating the treaty of peace in Paris, France, at the close of the American Revolution, had access to the records of French explorers and that he drew the boundary line through Lake Superior so as to include the copper deposits in the American possessions. He is reported to have said, "The time will come when drawing that line will be considered the greatest service I ever rendered my country." He did better than he knew, for he included the iron ore deposits as well. Several companies were organized for mining copper and silver in the Thirties and Forties, but it is stated that at the time of the Civil War only two were paying dividends. In 1865, the Calumet and Hecla Mining Company operations were started and from that time thousands of tons were produced annually. Until Montana and Arizona became important producers of copper, about 1880, Michigan was the principal source of supply in the United States. Iron ore was discovered near Marquette, Mich., in 1844, and, on a small scale, was reduced at the mines and shipped by water in the form of excellent iron.

Until 1855 through commerce from Lake Superior was blocked by the rapids in the St. Marys River. Previously, a small quantity of ore was moved from the mines near Marquette by wagon to the Lake, loaded aboard a schooner and taken to Sault Ste. Marie where it was unloaded, carried around the rapids, and reloaded on another vessel.

The State of Michigan, with funds obtained from the sale of lands under a Federal land grant, constructed a canal with locks around the rapids and opened it to commerce in 1855. The first through shipment of iron ore to an Erie port was made in the same year in the brigantine, *Columbia*. The panic of 1857 arrested development temporarily, but the Civil War created a great demand for iron with which to arm, equip, and supply the largest Army and Navy which up to that time the nation had ever been called upon to raise and maintain. Thus, again, Lake transportation became an important factor in military operations and contributed materially to their successful conclusion.

The opening of the St. Marys River to through water transportation made the Lake Superior lumber available to Eastern and Chicago markets. Duluth, Minn., and Superior, Wis., at the head of the Lake, came into being as supply points for lumbermen and, in 1870, were dependent on the lumber business. However, in 1871, wheat began moving from Northern Minnesota by Lake and, rapidly thereafter, with the settlement of North Dakota and Montana, they became the outlet for grain from these States, as well as from Northwestern Minnesota destined for the Eastern markets and for export.

At the close of the Civil War the great era of railroad building throughout the United States required an enormous supply of iron. To meet it, furnaces were built and expanded in the area between Lake Erie and the Monongahela River, where ore by Lake and coal by rail and river could be brought together with a minimum of expenditure of time and money. Thus, the great steel industry in Western Pennsylvania, Ohio, and West Virginia was built by low-cost transportation, combining to the best advantage both rail and water movements. Later, the same principles caused the developments in the steel industry at East Chicago, Indiana Harbor, and Gary, Ind.

Prior to 1884, only the Michigan and Wisconsin ranges were worked, but in that year shipments began from the ranges in Northern Minnesota, which had been discovered about 1875. The Minnesota ores moved and continued to move to Two Harbors, Minn., Duluth, and Superior, for loading into vessels.

With the settlement of the Upper Lake States and the development of industries therein, a demand for coal was created which could be met most economically by combining rail and water movements. Thus, at low costs for transportation, the bituminous coals of Western Pennsylvania, West Virginia, Kentucky, and Ohio have been marketed in ever-increasing quantities throughout the Upper Lake region, farther west in the United States and, to a considerable extent, in Canada.

By 1914, all Europe was at war, and by 1917 the United States was also in the struggle. For two years, the demand of the Allied Powers for steel for arms and munitions was tremendous and then the immense requirements of the United States Government to construct ships and to arm and supply the

Army and Navy were added. The great system of Lake and rail transportation which had been developed in the century since Commodore Perry's victory in 1813, met every requirement of the emergency and had an incalculable weight in the favorable outcome of the war. As long as the iron mines on Lake Superior and the coal mines last, and as long as wars are still a possibility, the transportation system built around water carriage on the Great Lakes will continue to be one of the greatest elements of military and naval strength, better appreciated, perhaps, by the possible enemies of the United States.

The Transportation System

A water-transportation system, such as that of the Great Lakes, consists of many elements: The Lakes themselves, their connecting channels both natural and artificial, connecting canals, the harbors and harbor terminals, with their mechanical and other equipment, the railroad facilities serving the harbors and reaching inland, the maintenance of channels and harbors, the vessels in the carrying trade, harbor craft, shipyards, aids to navigation, lighthouses, radio beacons, fog signals, ranges and buoyage, life-saving and distress service, navigation charts and the organizations and men who operate and maintain the vessels, and all the other elements of the system.

It is impossible in a short paper to describe the development and present status of all these elements in detail. However, it may be stated that all of them are in existence and are operated with high efficiency.

Channels and Harbors

In their original condition, each of the Great Lakes in itself afforded easy navigation, but connecting channels were either non-existent or inadequate. The first Welland Canal completed by the Canadians in 1829 opened navigation between Lake Ontario and Lake Erie. It had a depth of 8 ft. The first canal around the Falls at the "Soo" was opened in 1855, with a depth of 11.5 ft, connecting Lake Huron and Lake Superior.

There were almost no natural harbors so located along the American shores as to be of commercial value, so the Congress promptly began to authorize the improvement of channels and the construction of harbors by the War Department. For the small sailing vessels and steamers, the rivers and creeks on which the growing Lake communities were located were the only harbor possibilities within the financial abilities of the National Government. In general, the mouths of such waterways were obstructed by bars on which there was as little as 3 or 4 ft of water. Some examples of early harbor improvements are as follows:

(1) A survey of Erie Harbor, where a deep natural bay existed, was made by the Corps of Engineers in 1819 and showed only 6 ft on the bar. By Act of Congress in 1823, a board of officers developed a plan for the improvement of the entrance by dikes and jetties, and work was begun in 1824. By 1828 a minimum depth of 7 ft at all times had been obtained, which was increased to 9 ft in 1830 and to 13 ft in 1868.

(2) Work was begun at the mouth of the Oswego River in 1827.

(3) At Chicago, work at the mouth of the Chicago River was begun in 1833 by the construction of jetties, and a depth of 9 ft was obtained before 1840.

(4) At Lorain, Ohio, parallel jetties were built at the mouth of Black River, work beginning in 1828, and a depth of 10 ft was secured, the original depth having been 3 ft.

(5) Work to improve the entrance to the Cuyahoga River at Cleveland, Ohio, by parallel jetties was begun under the Act of 1825. The original depth of 3 to 4 ft was increased to 6 ft in 1828 and to 10 ft in 1831.

(6) In 1826, work was begun on piers at the mouth of Buffalo Creek, at Buffalo. In practically all these jetties or piers (Items (1) to (6)), timber work filled with stone was utilized for reasons of cost. The Federal Government limited its work to providing entrance channels. The municipalities and vessel operators took care of the channels inside the jetties.

(7) A depth of 12 ft was obtained through the St. Clair Flats in Lake St. Clair in 1855, where the original depth had been from 2 to 6 ft, and St. Marys River was deepened.

(8) By 1869, vessels had so increased in size and number that the need of outer breakwaters to afford anchorages and safety of entrance into the rivers was apparent. Work was begun on the Buffalo breakwaters in 1869, and on those at Chicago in 1871. Timber cribs filled with stone were the standard construction for the earlier breakwaters and most of them, later cut down to low water and capped with concrete, are still in service.

From these modest beginnings, designed to meet the immediate needs of a rapidly growing commerce carried in small vessels, steady progress has been made in deepening and widening connecting channels, in deepening harbors and their entrances, and in giving them more extensive breakwater protection in order to keep pace with the increase in size and draft of the Lake carriers. This has been possible at reasonable costs through the use of the most modern dredging equipment and the substitution of rubble, concrete caissons, and cellular steel shell-pile construction for timber cribs in breakwaters, as the price of timber became excessive.

At the present time (1938), the Lake System consists, in addition to adequate harbors, of down-bound connecting channels 25 ft or more in depth from the head of the Lakes at Duluth-Superior and from Chicago, to Ogdensburg on the St. Lawrence River, with 14-ft channels in the Canadian canals to Montreal, and up-bound channels 21 ft deep. The New York State Barge Canal 12 ft deep from Buffalo and Oswego to the Hudson, being deepened to 14 ft between the Hudson and Oswego, and the Illinois Waterway with a 9-ft depth, are important connecting waterways to the east and south.

Wherever possible, the up-bound and down-bound channels have been separated for safety to vessels. The existing project for the Upper St. Marys River provides for a two-way channel having a minimum width of 1 000 ft, with a depth at low-water datum of 27 ft through Round Island Shoals and

Middle Ground, and 26 ft through Vidal Shoals, widening to 1 200 ft at Brush Point Turn and thence, to Point Louise with a width of 1 000 ft.

The American locks at the "Soo" have the characteristics shown in Table 1. The Canadian Canal at the "Soo" is 1⅛ miles long, 150 ft wide at the top, 142 ft at the bottom, and has a lock 900 ft long and 60 ft wide. Navigation in the canal is limited by the depth over the miter-sills at the locks to boats with drafts of about 17 ft. It was opened to navigation in 1895.

In the Lower St. Marys River, the project provides for a down-bound channel with a depth of 25 ft and a minimum width of 300 ft, and an up-bound channel with a depth of 21 ft and a minimum width of 500 ft. In St. Clair River, the minimum width of the two-way channel is 600 ft, and the depth is 25 ft. In St. Clair Lake the two-way channel is 800 ft wide and 25 ft deep, narrowing to 700 ft at the mouth of the South Channel of St. Clair River.

TABLE 1.—CHARACTERISTICS OF THE AMERICAN LOCKS AT SAULT STE. MARIE, MICHIGAN (DIMENSIONS ARE IN FEET)

Locks	Clear width	Length between miter sills	Lift	Depth on Breast-Wall		Type of construction	Year completed
				Upper	Lower		
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
Weitzel.......	80*	515	21.7	15.8	11.2	Stone masonry	1881
Poe..........	100	800	21.7	21.8	16.6	Stone masonry	1896

Fourth.......	80	1 350	21.7	24.3	23.1	Concrete	1919

* 60 ft at the gates.

The two-way channel at the head of Detroit River is 800 ft wide and 25 ft deep. Fighting Island Channel, below Detroit, is 26 ft deep and 800 ft wide; Ballards Reef Channel north of the junction with Livingston Channel is 26 ft deep and 600 ft wide. The Livingston Channel west of Bois Blanc Island for down-bound vessels, is 450 ft wide and 26 ft deep to opposite Bar Point, thence 26 ft deep and 800 ft wide to its junction with Amherstburg Channel, and thence 26 ft deep and 1 200 ft wide to the 26-ft depth contour in Lake Erie, the lower 1 200-ft section being used for both up-bound and down-bound traffic. Amherstburg Channel, east of Bois Blanc Island, for up-bound vessels, is 21 ft deep with a minimum width of 600 ft.

The new Welland Canal, opened in 1932, is 25 miles long, with a bottom width of 200 ft, 310 ft at the water line, and a depth of 25 ft. The canal has seven locks, each having a usable length of 820 ft, a width of 79 ft, and a depth of 30 ft over the sills.

SHIPPING

The great length of the connecting channels in which natural depths were small and the artificial character of the Lake harbors built in comparatively shallow water have made it impracticable to provide depths for Lake navigation equal to that at ocean ports. Storm waves on the Lakes probably never much exceed a height of 20 ft from trough to crest. Most of the freight is handled in bulk. Docks and their unloading equipment, once installed, can be modified only at great expense.

Channel and harbor depths have limited the draft of vessels, dock equipment has limited their beam, and safe handling in restricted waters has limited their length, although the moderate height of storm waves has permitted ratios of length to beam and to depth greater than ocean practice. As a result of all these factors a bulk freighter has been developed with large rudder power, which can carry about as much on 22-ft draft as large ocean vessels can carry on 30 ft, or more. This development, of course, has been gradual with improvements in ship construction and with the increase in depths of channels and harbors.

The first vessels on the Lakes were sailing schooners and brigs; then came wooden-paddle wheel steamers. The *Ontario*, the first American steamer on the Lakes,[2] was built in 1816. It was 110 ft long, with 24 ft beam, 8½ ft depth, a displacement of 237 tons, and was driven by one low-pressure cylinder with a bore of 34 in. and a stroke of 4 ft. It is stated that it took her ten days to make the trip from Lewiston to Ogdensburg. The *Vandalia*, the first propeller boat in the United States, was built in Oswego in 1841. For years, commerce was carried in sailing vessels, towed through the rivers by tugs, in steamers, and in steamers with one or more barges in tow. Hulls went through the evolution in design from wood, to composite wood and iron and steel, and then to steel. The steel whaleback freighter and whaleback barge had their day, but since about 1904 the type of bulk carrier has been well established, the changes being only in their size.

The carrying capacity of Lake bulk freighters on a 19-ft draft ranges from 3 000 to 12 000 short tons (see Items Nos. 1 to 3, Table 2). The extra load per foot of draft, up to 22-ft draft, varies from about 1 000 to 430 net tons. These vessels are usually constructed with the deck-house and high bridges forward, a cargo hold, without bulkheads, and a coal-burning power plant aft. The hatches over the cargo hold are spaced on about 12 ft centers. Trim of the vessels and safety are provided by inside tanks.

Four bulk freighters built during 1937 and 1938 have a carrying capacity on 22-ft draft of 15 440 short tons (Items Nos. 4 to 7, Table 2). They are equipped with geared turbines of a capacity sufficient to obtain speeds of 12 miles per hr loaded and 13.5 miles per hr light. The Canadian steamer, *Lemoyne* (Item No. 8, Table 2), the largest of the Lake fleet, has carried record cargoes in net tons, as follows: Ore, 16 400; bituminous coal, 16 500; anthracite coal, 14 600; stone, 18 100; and, wheat, 17 100.

Self-Unloaders.—In 1928 there were 43 self-unloading vessels on the Great Lakes, with a gross tonnage of 144 730, which were increased to 65 vessels having a gross tonnage of 243 343 in 1937. Many of these vessels are of the usual ore and coal-handling types with cargo hoppers installed in their holds, discharging on to belt conveyors and through a bucket elevator on to a belt conveyor carried on a long boom, which is swung outboard when unloading cargo. Loads from the large vessels can be placed 115 ft from shipside at an elevation of 65 ft above deck level.

---

[2] "Freighters of Fortune," Beasley, p. 50.

Motor Ships.—There are 48 motor-operated vessels in bulk and package-freight services on the Lakes, with gross registered tonnages ranging from 1 000 to 8 877, of which 36 are of American registry and 12 Canadian. The two largest, the *Henry Ford II* and *Benson Ford*, are both bulk freighters, of the standard Lake type, propelled by Diesel engines (see Items Nos. 9 and 10, Table 2).

TABLE 2.—TYPICAL VESSELS IN THE GREAT LAKES TRADE

Item No.	Name of vessel	Year built	DIMENSIONS, IN FEET				Gross registered tonnage	Type
			Length	Breadth	Draft loaded	Depth of hold

15	*Chester*	1931	291	43	12.5	15.7	1 819	Lake and canal freighter
16	*Badger State*	1912	250	43	10	16.7	1 539	Lake and canal freighter
17	*Panoil*	1920	242	37	18	19.7	1 370	Typical Lakes tanker

Passenger and Package Vessels.—On December 30, 1934, there were 119 vessels of 1 000 gross tons and upward, aggregating 357 231 tons, in the passenger and package freight trade on the Great Lakes. The *W. J. Conners* (Item No. 11, Table 2) is probably typical of this class of vessel. It is powered with an 1 800-hp, quadruple expansion, steam engine, giving it a speed of 13 miles per hr.

Automobile Carriers.—This type of vessel was converted from the bulk freighter. They were converted by the addition of "'tween decks" and elevators for the lowering of cars to the lower decks. A representative vessel of this type is the *Crescent City* (Item No. 12, Table 2). In 1936, a similar conversion was made on the *James Watt* (Item No. 13). This vessel is a pioneer in a rather unique transportation plan—the carrying of loaded truck trailers between Detroit and Cleveland.

Tankers.—Tanker tonnage on the Great Lakes now constitutes one of the important items of traffic. No individual type has been developed in this trade with the exception of the motor tanker that trades on the New York State Barge Canal and the Great Lakes. Several of the tankers in use on the

Great Lakes have seen prior service on the ocean. A typical tanker on the Great Lakes is the *Panoil* (Item No. 17, Table 2), with a speed of 10 miles per hr loaded and 12 miles light.

A large group of Diesel-powered tankers are operated on the Great Lakes by one of the more important oil companies. All these boats are of the New York Barge Canal type, whose general characteristics are a rather excessive breadth, a length of 250 ft, a draft limited to approximately 12 ft, with a speed of approximately 9 miles per hr, and a carrying capacity of approximately 11 000 bbl.

New York State Barge Canal-Boats.—Because of the peculiar physical conditions to be met, a distinct type of boat has been developed for this traffic. All these self-propelled vessels are Diesel-powered with the exception of two boats, the *Edgewater* and the *Chester* (Items Nos. 14 and 15, Table 2). A typical vessel of this type is the *Badger State* (Item No. 16), which draws 10 ft of water, loaded. The power is a Diesel engine of 930 ihp. The cabins are set through the deck with about one-half their height projecting above the main deck. The hold is divided into compartments and closed with the conventional type of hatches.

Items Nos. 14 and 15, Table 2, are more elaborate in construction than other boats in this trade. Power is supplied with two oil-fired water-tube boilers to steam turbines, developing 1 600 shaft hp. The pilot-house is on an elevating mechanism that raises and lowers it. When operating in the canal, the pilot-house is lowered to pass under the bridges, and, in the Lakes, it is raised to give better visibility.

The records show that in 1868, the total number of documented American vessels, exclusive of canal-boats, amounted to 2 543, with a gross tonnage of 454 051, averaging 178 tons per vessel. In 1935, there were 550 American vessels of 1 000 gross tons and more, with a total gross tonnage of 2 575 455, of which 441 were classed as bulk freight carriers, exclusive of tankers, having a gross tonnage of 2 231 883, or 87% of the total tonnage. Canadian vessels of 1 000 gross tons and more numbered 285, having a total gross tonnage of 733 971, of which 221 were classed as bulk freight carriers, aggregating 574 903 gross tons, or 78% of the total gross tonnage.

AIDS TO NAVIGATION

The United States Lake Survey (War Department[3]) publishes for sale and keeps up-to-date general navigation charts of each of the Great Lakes, of Rainy Lake, Lake of the Woods, the New York State Barge Canals, and Lake Champlain, and detailed charts of all harbors and connecting channels and of the St. Lawrence River from Lake Ontario to the International Boundary. It also publishes annually a *Bulletin*, supplementing information given on charts, containing detailed descriptions of shores, outlying shoals, harbors, storm warning, and Coast Guard stations, together with changes in channel conditions and buoyage. The Survey is constantly engaged in sweeping for shoals and wrecks, revising charts, and making observations of Lake levels and river discharges.

---

[3] See, Manual of Engineering Practice No. 7, Am. Soc. C. E., Fig. 1, p. 5.

The United States Bureau of Lighthouses (Department of Commerce) has installed and maintains a most modern system of lights, radio beacons, fog signals, ranges and channel buoyage throughout the American waters, harbors, and connecting channels of the Lakes and of the St. Lawrence River. Any changes in lights or buoyage or any other aids are immediately made known to navigators by that Bureau. The Canadian Government performs a similar service in Canadian waters.

The Coast Guard maintains a system of life-saving stations at all important points throughout the Lakes and a fleet of two 165-ft cutters and seventeen patrol boats for the enforcement of Federal laws, for assisting vessels in distress, and for protecting life and property upon the navigable waters of the United States. It also operates, through arrangements with commercial telephone and radio companies and its own radio, a system of communication for vessels in distress.

The United States Weather Bureau operates a system of storm warning stations and forecasts for the Lakes region especially applicable to navigation.

MAINTENANCE OF CHANNELS, CANALS, AND HARBOR WORKS

For the maintenance of channels, canals, and harbor works, and the construction of new works, the War Department maintains five Districts with District Offices in Duluth, Milwaukee, Chicago, Detroit, and Buffalo. The Lake Survey, operated as a District covering the entire Lake region, is also situated at Detroit. All District Engineers are supervised by a Division Engineer, with office in Cleveland, who reports to the Chief of Engineers, U. S. Army, in Washington, D. C. New work of constructing breakwaters or channel dredging is done by contract, and the marine contractors on the Lakes have the most modern equipment for such work.

The War Department maintains four sea-going hopper dredges for the maintenance of harbors, and sufficient other plant to do repair work on breakwaters. Each District Engineer is responsible for the maintenance of project depths in the Government channels in his District and for performing other duties relative to navigation charged by law to the War Department.

HARBOR TERMINALS

There is nothing remarkable about the package freight terminals on the Lakes. The bulk freight terminals, however, are unusual in their excellence of mechanical equipment, capacity, and efficiency. The ore-loading docks are designed with their ore pockets spaced so as to cover the hatches of vessels. The unloading docks for ore are laid out and equipped so as to take ore from vessels and load it directly to railroad car, or into stock-piles. Car dumpers for coal from rail to vessel are of the best design. The bulk terminals in general have been installed by the railroad companies and are supported by adequate and well laid out storage and switching trackage. The efficiency of the Lake system of transportation is due to a combination of economical water haul with highly efficient terminal and railroad operation, making possible the quick turn around of vessels during a seven-month navigation season.

The combined efficiency of terminals and vessels is shown by the records in Table 3. The records of the Lake Carriers' Association show that the average stay of iron-ore carriers at Lower Lake ports has decreased from 36 hr in 1906 to less than 11 hr in 1937. Corresponding figures for ore carriers at loading ports are 22.5 and 4.2 hr.

TABLE 3.—COMBINED EFFICIENCY OF TERMINALS AND VESSELS

Commodity (1)	Unit (2)	(a) Loading Vessels		(b) Unloading Vessels	
		Quantity (3)	Time, in hours (4)	Quantity (5)	Time, in hours (6)
Ore	Gross tons	12 508	0.28	12 009	2.42
Coal	Net tons	11 293	3.5	9 366	6.08
Wheat	Bushels	157 565	1	451 382	15

VESSEL OPERATORS AND CREWS

The Lake Carriers' Association was organized at Buffalo in 1892 and was incorporated in 1903. The purpose of the Corporation as set forth in the Charter is:

> "To establish and maintain assembly rooms for the use and general welfare of seamen on the Great Lakes, their connecting and tributary waters; to establish and maintain and procure the establishment and maintenance of aids to navigation; and improve and secure the improvement of channels, docks, wharves, loading and unloading and terminal facilities; to establish and maintain by contract or otherwise such amicable relations between employers and employed as will avoid the public injury that would result from lockouts or strikes in the lake carrying service; to provide for the prompt and amicable adjustment of matters affecting shipping and the interests of vessel owners of the Great Lakes and their connecting and tributary waters, and to lease, rent, purchase or sell such real or personal property as may be necessary or convenient in carrying out the foregoing purposes."

The liberality of view in this statement of purpose and the success of the Association in accomplishing it are remarkable. It has demonstrated how such an Association can be of great service to an industry by studying its problems, improving the conditions of its employees, and presenting facts to the Government agencies with which it has to deal.

The recommendations made by the Association for improvements for the benefit of shipping on the Lakes have consistently been constructive and conservative. At the time of incorporation the membership included passenger vessels, tugs, and sailing ships. On December 31, 1937, the membership included mainly the bulk freight vessels of American registry in the iron ore, coal, grain, and stone trades, as follows:

Bulk freight steamers and motor ships	311
Self-unloading bulk freighters	33
Package freighters	2
Tankers	15
Barges	13
Towing tug	1
Total	375

The total gross registered tonnage of the vessels enrolled in the Association is 2 080 850, or 81% of the total United States gross registry of commercial vessels on the Lakes. The carrying capacity for a single trip at prevailing drafts is approximately 3 000 000 gross tons.

Growth in Tonnage of Lake Vessels

The number and gross tonnage of vessels enrolled in the Lake Carriers' Association at 10-yr periods, with the change in average tonnage, are as shown in Table 4. In certain cases the Association has expended its own funds for dredging in channels, and the establishment and maintenance of lights, buoys, and lightships when the Government was not in a position to do so.

TABLE 4.—Vessels Enrolled in the Lake Carriers Association

Year (1)	Number of ships (2)	Gross registered tonnage (3)	Average per ship (4)	Year (1)	Number of ships (2)	Gross registered tonnage (3)	Average per ship (4)
1893...	612	579 919	946	1925	423	2 223 143	5 255
1905...	542	1 411 749	2 605	1935	397	2 185 822	5 500
1915...	428	2 012 593	4 700	....	..	......	....

In 1908, it established a welfare plan for the benefit of sailors, providing for assembly rooms in the principal ports, equipped with current newspapers, magazines, writing materials, and other conveniences, and for the payment of death benefits from accidents incident to employment. The Association maintains an excellent library at the "Soo" and exchanges books with its vessels as they pass through the locks. Through its Committee of Shore Captains, composed of a group of masters with long experience in lake navigation now filling executive posts, its Committee on Aids to Navigation, composed of active masters, and its Fleet Engineers' Committee, made up of former chief engineers now supervising the Engine Departments of the vessels in their respective fleets, the Association is constantly working for safer and better operation and better maintenance and construction.

It has established for its member vessels up-bound and down-bound courses in Lakes Huron, Michigan, and Superior, which also are generally followed by non-Association vessels, thus reducing the hazards of collision in fog.

For twenty years the Association has conducted schools, during the closed season, for the wheelsmen and oilers in its fleet desirous of advancement to officer rating, and for officers desirous of raise in grade. During that period 730 oilers and 544 wheelsmen obtained their original licenses, and more than

1 800 Lake seamen who attended the schools obtained the license for which they were instructed.

The scale of wages paid on Association vessels in 1937 was as follows:

	Per 30-day month		Per 30-day month
Wheelsman	$118.50	Chief cook (on vessels of more than 4 000 tons)	$183.00
Watchman	115.50	Chief cook (on vessels of less than 4 000 tons)	162.00
Deck watch	102.00	Second cook	105.00
Deckhand	87.00	Porter	87.00
Fireman and oiler	115.50		
Coal passer	81.00		

During the World War, under arrangements made with the U. S. Navy Department, 3 503 men were trained aboard the Association's vessels for positions in the Navy and the Shipping Board. In addition, the Association responded to every call from the Emergency Fleet Corporation to provide crews for the ships built or purchased on the Lakes by the Government for ocean service in the war. The offices of the Association furnished 1 934 men for the 112 vessels.

FREIGHT AND PASSENGER TRAFFIC

Now, "the proof of the pudding is in the eating," and the efficiency of any system must be judged by the results. In this sense, the record of the volume of commerce on the Great Lakes and the cost of water transportation speak for themselves.

The freight passing through the canals at the "Soo" (which is the best index of Lake transportation) was only 14 500 tons in 1855; the 500 000-ton mark was passed in 1870; in 1876 more than 1 000 000 tons of traffic utilized this route; and the peak was reached in 1929, when more than 92 000 000 tons of freight passed through the locks.

During the decade, 1926–1935, the average annual commerce of the United States Great Lakes ports was 114 837 300 short tons, which included the highest as well as the lowest tonnages in recent years, with 161 344 361 tons in 1929 and 54 913 140 tons in 1932. After eliminating all known duplications, the net traffic on the Great Lakes in 1936 amounted to 138 373 898 short tons, valued at $1 907 952 846.

Passenger traffic at the United States ports on the Great Lakes consisted largely of ferry passengers during the decade, 1926–1935, and averaged more than 19 000 000 persons, of which 58.5% arrived at, or departed from, Detroit; 20.2% were handled at Lake Erie ports; 6.6%, at Lake Michigan ports; 5.1%, at Port Huron; 5%, at localities on the St. Lawrence River; and the remainder at other Lake ports.

Some idea of the traffic on the connecting waterways of the Lakes can be had from the following data: During the 81 yr from 1855 to 1935, the St. Marys Falls Canal has transited a total of 2 394 472 474 tons of freight, or an average of 29 561 389 tons per year during its existence; the St. Clair Flats Canal, in Michigan, in 1891, transited 22 160 000 tons, which increased to a peak of 99 677 966 tons, in 1929, and, in 1935, amounted to 59 287 907 tons;

the Detroit River with 23 209 619 tons in 1891, reached its high level of 110 719 845 tons in 1929 and, in 1935, shows a total of 75 779 280 tons; the Welland Ship Canal showed a movement of 719 360 tons in 1900, and a peak of 9 280 452 tons in 1929, whereas the 1935 traffic amounted to 8 537 460 tons; the New York State Barge Canal traffic since 1837 (or during 99 yr) amounted to 363 641 280 tons, or an average of 3 673 144 tons per yr. The largest recorded traffic was moved in 1871, when 6 467 888 tons were handled, and the smallest, or 1 159 270 tons, in 1918. Since 1918 the movement has increased to its 1936 volume of 5 014 206 tons; traffic on the St. Lawrence River Canals saw its peak in 1928, when 8 411 538 tons were handled, whereas the traffic since that time has ranged from 5 718 651 to 6 951 064 tons, with a recorded total of 6 873 655 tons handled in 1933, of which 4 879 714 tons originated in Canada and 1 993 941 in the United States.

The Grain Movement.—The territory tributary to the Great Lakes is the most important grain-producing district in the world. It includes most of the surplus grain-producing States of the United States and nearly all the grain territory of Canada. This territory in 1928 produced 35.1% of the world's grain, excluding that of Russia and China, but, in 1935, production had dropped to 28.7 per cent. The sixteen States included within this territory have produced 71% of the wheat grown in the United States since 1919. The enormous quantity of grain flowing eastward is practically all shipped through the four ports of Fort William-Port Arthur, Duluth-Superior, Milwaukee, and Chicago. Shipments from the United States ports are of record from 1868, when a total of 48 585 bushels were shipped, and shipments from Fort William-Port Arthur began in 1884 with 951 bushels. The peak year in grain shipments from Upper Lake ports was in 1928 when more than 572 000 000 bushels were shipped. However, in 1935, shipments from these ports had dropped to 235 000 000 bushels. During the 16-yr period from 1920 to 1935 Fort William-Port Arthur shipped 49.6% of the grain from the four Upper Lake ports; Chicago, 25.1%; Duluth-Superior, 19.4%; and Milwaukee, 5.9 per cent. Wheat constituted 58.3% of the total grain shipments from the four ports; oats, 15.4%; corn, 12.8%; barley, 7.0%; rye, 4.8%; and flaxseed, 1.7 per cent.

Buffalo is the principal receiving port for grain at the Lower Lake ports. It received 200 000 000 bushels in 1928, and more than 104 000 000 bushels in 1935.

Port Colborne, Ont., Canada, is an important transfer point on the Lower Lakes for Canadian grain and received 20 600 000 bushels during 1935. However, since the construction of the new Welland Ship Canal and the construction of transfer elevators at Kingston and Prescott, Ont., Canada, grain en route to Montreal now goes directly to these points for transfer. Kingston received 12 000 000 bushels in 1935 direct from Upper Lake ports in deep-draft vessels, Prescott received 8 000 000 bushels, and Montreal received 51 000 000 bushels in vessels drawing not more than 14 ft of water.

The grain movement on the Great Lakes has changed considerably since 1928. The natural flow of grain has been from west to east, but reduced grain crops during the droughts of 1934, 1935, and 1936 resulted in shipments of grain from the seaboard to the grain-growing sections of the West. During 1928 there were shipments from the seaboard to the Great Lakes *via* the New York State Barge Canal of 230 688 bushels. In 1934, 1935, and 1936, the shipments by this route were 7 452 622, 9 620 572, and 3 671 361 bushels, respectively. In the same years the westbound shipments through the Welland Canal amounted to 11 662 490, 9 214 453, and 9 268 284 bushels, respectively.

In 1937, the westbound movement through the New York State Barge Canal amounted to 3 220 192 bushels and through the Welland Ship Canal to 32 101 679 bushels, a total of 35 321 871 bushels. The receipts at the Upper Lake ports totaled about 30 000 000 bushels and included 21 500 000 bushels of corn from Argentine Republic delivered at Chicago and Duluth-Superior and 1 239 477 bushels of flaxseed from Argentine Republic delivered at Duluth-Superior.

Iron Ore.—More than 1 600 000 000 tons of iron ore have passed down through the St. Marys Falls Canals since 1855. The peak year in the ore trade was 1929 when more than 72 000 000 short tons were handled. In 1936, the ore movement by Lakes was 50 176 000 short tons, of which 47 000 000 short tons passed through the United States locks at the "Soo" from the Superior ranges. The receipts of ore at Lower Lake ports in 1936 were as follows:

Port	Short tons	Port	Short tons
Detroit	1 720 000	Ashtabula	5 017 000
Toledo	1 693 000	Conneaut	7 586 000
Huron	789 000	Erie	1 721 000
Lorain	3 078 000	Buffalo	4 170 000
Cleveland	10 149 000	Port Colborne	77 000
Fairport	1 006 000	Hamilton	521 000

and at Lake Michigan ports there was received:

Port	Short tons
Indiana Harbor	2 527 000
Gary	3 630 000
South Chicago	6 016 000

The movement of ore from Erie ports to interior consuming furnaces is an all-rail movement. The greater bulk of the ore is loaded direct from ship to car. Cleveland, Conneaut, and Ashtabula, Ohio, are the leading Lake ports for shipment to the interior.

Coal.—In 1936, 44 000 000 net tons of bituminous cargo coal were carried, which was 6 000 000 tons more than had ever before been moved on the Lakes in a single season. In addition, the car dumpers put 1 430 000 tons of fuel into the bunkers of vessels which were loading coal. For the first time a single port —Toledo, Ohio—has loaded more than 20 000 000 tons of cargo coal. Sandusky, Ohio, loaded 9 355 000 tons. Shipments from these two ports were almost entirely coal from Southern mines. Shipments of bituminous coal from Lake Erie ports to, or through, the Welland Ship Canal, to a great extent to Hamilton and Toronto, Ont., Canada, reached 3 000 000 tons for the first time.

Distribution of Lake soft coal by districts was as follows:

District	Tons
Lake Superior	11 331 000
Lake Michigan	14 738 000
Lake Huron and Georgian Bay	1 918 000
Lower rivers	6 730 000
Lake Erie	5 057 000
Welland Canal	3 035 000

During 1937, 674 000 tons of anthracite were handled on the Lakes. The value for 1917 was 4 689 000 tons.

Limestone.—In 1936 the Lake movement of limestone amounted to 12 080 000 net tons.

Car-Ferry Traffic.—The first cross-lake service was inaugurated in 1892 between Frankfort, Mich., and Kewaunee, Wis. Since that time this method of transportation has increased until there are three lines operating on Lake Michigan, one on the Straits of Mackinac, three across Detroit River, between Detroit and Windsor, Ont., Canada, one each on Lakes Erie and Ontario, and one across the St. Lawrence River at Ogdensburg. These ten lines operate a total of thirty-five car-ferries, thirty-one of which are in active service. All the car-ferries, except those on Lake Erie, operate during the entire year, trips on Lake Erie being made as traffic demands. During the calendar year 1935, car-ferry traffic on Lake Michigan amounted to more than 3 000 000 tons.

A comparison of the traffic through the Suez, Panama, and St. Marys Falls Canals and of the commerce of three Lake ports is given in Table 5.

TABLE 5.—TRAFFIC OF MAJOR CANALS AND LAKE PORTS

Canal or port	1928		1929		1932		1935	
	Short tons*	Rank among United States ports	Short tons*	Rank among United States ports	Short tons*	Rank among United States ports	Short tons*	Rank among United States ports
(*a*) TONNAGE THROUGH THE SUEZ, PANAMA, AND ST. MARYS ("SOO"), CANALS								
Suez	31 905 902	..	33 466 014	..	26 049 554	..	29 021 354	..
Panama	33 022 935	..	35 320 308	..	20 334 758	..	27 746 588	..

* 2 000 lb

Ore.—During 1937 rates on iron ore from the mines at the head of Lake Superior to Lake Erie ports were as follows per gross ton:

Rail to Duluth-Superior and Two Harbors	$0.81
Dumping at dock	0.10
Carriage by vessel to Lake Erie ports and unloading charge to vessel rail	0.80
Vessel rail to car	0.08
Rail to Pittsburgh, Pa.	1.15
Rail to Youngstown, Ohio	0.82

Adding the terminal charges to the water haul gives $0.98 from port to port as against $1.96 for the two rail hauls for ore delivered at Pittsburgh, and $1.63 for ore delivered at Youngstown.

The 1936 vessel rates on coal from Lake Erie ports were as follows:

	Per net ton
To principal ports on Lake Superior	$0.40
To principal docks at Milwaukee	0.50
To principal docks at South Chicago and Indiana Harbor	0.50
To ports on Georgian Bay	0.35

Grain rates vary throughout the season, depending upon the volume of movement and competition for cargoes. The 1936 rates from Duluth-Superior to Buffalo fluctuated between 1.75 cents and 3 cents per bushel. Canadian grain rates from Fort William fluctuated between 3.5 cents and 5 cents to Montreal and between 1.5 cents and 1.75 cents to Buffalo, except for lake loadings when the rate jumped as high as 5 cents.

Cost and Savings

The total expenditures for new work by the War Department on the channels, canals, and harbors of the Great Lakes to June 30, 1937, is $193 573 686.83. It has been estimated by engineers outside the Government service that the savings in freight charges due to water transportation on the Great Lakes are considerably in excess of $200 000 000 per yr.

Conclusion

The existing system of industry and transportation which has been built up around water carriage on the Great Lakes in the last century is the result of the co-operative efforts of the Federal Government, the railroad companies, industries, municipalities, and vessel owners and operators during that entire period. In each decade the facilities provided for navigation and at the terminals have been reasonably adequate for the number and class of vessels in the Lake trade and for the tonnage moved. They have never been overbuilt; nor has money been spent extravagantly far ahead of requirements. As one examines the record, one must be impressed with the fact that the present results have been obtained by the application of good engineering practice and sound business judgment, and by planning for the future only as far as definite benefits could be foreseen.

DISCUSSION

T. KENNARD THOMSON,[4] M. AM. SOC. C. E. (by letter).—The French and then the English managed to reach Lewiston and Queenston, on the Niagara River, by water transportation with a few land portages, between Montreal and Lake Ontario (St. Lawrence River).

They encountered the first formidable portage, a climb of more than 300 ft and a land haul of about 30 miles, from Lewiston to near Buffalo. This afforded the main route for trade (chiefly with Indians) until the Canadians constructed the Welland Canal. The construction of the Erie Canal was due to the untiring and unselfish efforts of De Witt Clinton (1769–1828) who contributed his time and money without stint. No one else did nearly as much for the project. He started the construction of the Canal in 1817, and completed it in 1825.

The Erie Canal, as then built, was 4 ft deep, 40 ft wide, and was used by boats of from 30 to 70 tons. By 1825 it had earned its entire cost of $7 143 789, and, at the same time, greatly reduced the freight rates, thereby enormously increasing the population and wealth of the State. By 1862 the Canal had been deepened to 7 ft for boats of 240 tons. The enlargements from 1837 to 1862 cost $31 834 041. Work was started to increase the depth to 9 ft, but it was not completed.

The cost to 1899 was $48 000 000. In 1881 all tolls on the Canal were abolished. Prior to that time the net revenue had exceeded all costs by $42 000 000. The Barge Canal was started in 1904 and completed to a depth of 12 ft in 1918, at a cost of $170 000 000. Prior to 1908 the revenue from the Canal had been about $360 000 000, or $20 000 000 more than the total cost to that date.

Under the heading, "Shipping: New York State Barge Canal-Boats," General Tyler states that "because of the peculiar physical conditions to be met, a distinct type of boat has been developed." The writer presumes that he refers to the limited height under the bridges, which make it a "Barge Canal."

The reason for changing the Erie Canal to a "Barge Canal" was that the politicians were afraid that New York, N. Y., and Buffalo, N. Y., would vote against the proposed enlargement, if ships could pass through the Canal without being unloaded and loaded at Buffalo and New York. Hence a "Barge Canal" was constructed, with fixed bridges that make it impossible for any boat standing 15.5 ft above the surface of the water to pass under the bridge.[5]

Another mistake made on the Barge Canal was in not relocating the line near Rome, N. Y., so that it would be unnecessary for all boats from Buffalo to "lock up" about 50 ft, before "locking down" again. As it is, water from Lake Erie cannot reach the Hudson River, and it was necessary to create great artificial lakes, by dams at Delta, N. Y., Hinckley, N. Y., etc., to supply water for the Canal east of the hump.

---

[4] Cons. Engr., New York, N. Y.

[5] *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 867.

For many years there has been talk about constructing a ship canal from the Hudson River to Lake Ontario or Lake Erie, so that ocean-going vessels could reach the Great Lakes. Before the depression (1930) it was estimated that such a ship canal would cost $650 000 000. As the Americans can use the new Canadian Welland Canal—the best route for the ship canal would be from the Hudson River to near Oswego, N. Y., on Lake Ontario.

General Tyler states that the entrance to Buffalo Creek was improved in 1826, and that the Government breakwater in front of Buffalo Creek was constructed in 1869 (see heading, "Channels and Harbors," Improvements (6) and (7)). As Buffalo still has a very inadequate harbor, the writer has, for many years, been advocating the reclamation of from 6 to 10 sq miles from Lake Erie, just outside the Government breakwater, for a great railroad and shipping terminal.

As Buffalo will eventually extend from Lake Erie to Lake Ontario, it will then have two ports for ocean-going vessels, one at Elevation 242, and the other at Elevation 576, above sea level.

As the author states (see heading, "Channels and Harbors"), the enlargement of the Welland Canal, with a depth of 25 ft of water was completed in 1932. Many wonder why this well-constructed canal was built to such a depth before the St. Lawrence River was developed, when boats drawing less than one-half that depth of water could not reach Lake Ontario from Montreal, and could not enter many of the Lake ports. Some say that it was due to "keeping sub-election promises."

As stated in the paper, the important commerce over the Barge Canal now consists of coal, ores, wheat, etc. In the earlier days it was mostly for Indian trade which was for many years controlled by the Great Hudson Bay Company.

It is now claimed that ores can be delivered in New York Harbor, *via* the Lakes and the Barge Canal, at a smaller freight charge than they can be delivered in Pittsburgh.

The indispensable test of all construction should be the question: "Will it pay?" The only way in which this condition can be met in developing the navigation facilities of the St. Lawrence River, to permit ocean-going vessels to reach Lake Superior, will be by developing the water power of the Niagara and St. Lawrence Rivers.

For twenty-seven years, the writer has been advocating, a dam ("Niagara Falls Junior") to be located about 4.5 miles down the river from the Old Falls, or below the Whirlpool.[6] For about the same time, he has also been advocating the reclamation of about 10 sq miles from the St. Lawrence River, between Lachine and Montreal, Que., Canada, and the development of 1 500 000 hp, hydro-electric, at that site.

If these projects are constructed economically, as they should be, industries will be attracted sufficient to create a dozen Pittsburghs along the banks of the Niagara and St. Lawrence Rivers, bringing great financial prosperity to the entire continent of North America and benefitting many other parts of the world.

---

[6] "Niagara Falls, Jr.," an interview with T. Kennard Thomson by G. P. Roney, *The Banker and Financier*, September 15, 1921.

HARLAND C. WOODS,[7] M. AM. SOC. C. E. (by letter).—In connection with this paper, it is of interest to note how the developments in bulk freighters have influenced the design of locks at Sault Ste. Marie, Mich. In the early days, freight carriers were general cargo ships suitable for navigating the relatively shallow connecting channels of the central Great Lakes. With the development of the ore, grain, coal, and limestone traffic, the bulk freight carriers were gradually evolved. At first, the dimensions of vessels were gradually increased in conventional ocean-going craft proportions. As the bulk freighter type of vessel emerged, widths were limited by the distance from the face of the dock within which it has been found economically practicable for the unloading machines to operate. This has been found to be less than 70 ft. Structural strength of the vessel limits the depth of hull proportionally to the width. For large vessels the maximum has been found to be about 32 ft. With width and depth defined, the length of vessels has been limited by structural requirements and practical thickness of deck plates to about 600 ft to enable a fully loaded vessel to "ride out" Great Lakes storms safely.

The grain and ore movement involves passage through the St. Marys River and the locks at Sault Ste. Marie. As vessels increased in size, larger locks were built. Fig. 2 indicates, chronologically, the parallel development of vessels and locks. Experience has shown that the lockage of more than one vessel at a time is most expeditious and safe if vessels are tied stem to stem in the lock rather than side by side. Hence, the latest locks built are slightly wider than the maximum width of vessel and long enough to accommodate two of them. Until new developments in trade, vessels, and cargo handling equipment appear, there is little prospect of changes in dimensions of vessels and locks.

W. L. R. HAINES,[8] M. AM. SOC. C. E. (by letter).—An able and concise presentation of an historical and statistical review of transportation on the Great Lakes has been presented by General Tyler.

One factor contributing very largely to the efficient and economical development of freight transportation—particularly of ore and coal—on the Lakes is deserving of special emphasis; that is, the great flexibility of the transportation system, combining water haul with rail haul. This is made possible by the development of numerous transhipping docks along the southern shore of Lake Erie, by the railroads. Such facilities offer shippers a wide range of choice as to rail routes between Lake Erie and the consuming or producing districts. They make it possible to divert vessels or cars from one transhipping dock to another in order to avoid delays to vessels which might result from congestion or break-down of facilities at a given dock.

Those interested in the location and ownership of these docks are referred to a report prepared by the Board of Engineers for Rivers and Harbors in 1937.[9]

[9] "Transportation on the Great Lakes," prepared by the Board of Engineers for Rivers and Harbors, *Transportation Series No. 1* (revised 1937); published by the U. S. Government Printing Office, Washington, D. C.

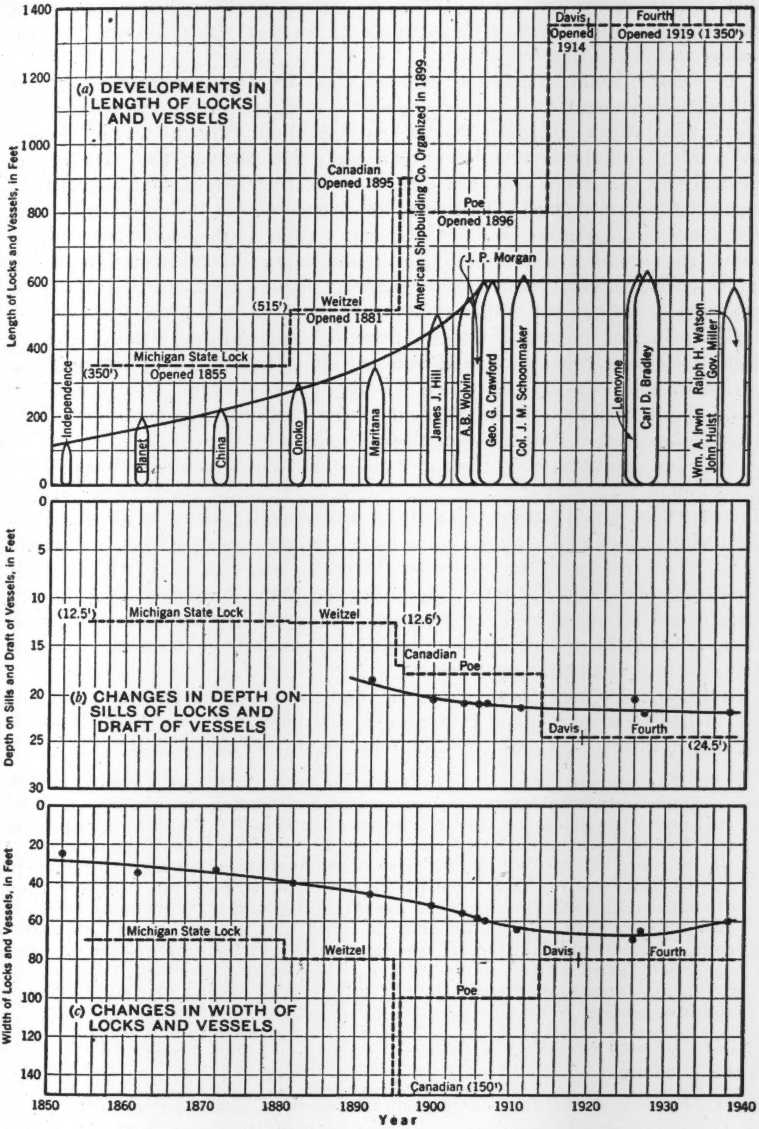

FIG. 2.—CHRONOLOGICAL DEVELOPMENT IN DIMENSIONS OF LAKE BULK FREIGHTERS AND LOCKS AT SAULT STE. MARIE, MICH.

This and an earlier edition of the same report (dated 1930) contain maps devised to illustrate the flow of ore and coal between Lake Erie and the consuming and producing districts.

For many years there has been agitation for the construction, by the Federal Government, of a canal between Lake Erie and the Ohio River, the most favored route being from a point near Ashtabula, Ohio, by way of Youngstown, Ohio, and the Beaver River to a point near Beaver, Pa. The cost of constructing this canal has been estimated by the Government engineers at about 203 million dollars. This sum, however, does not include facilities and equipment for operating and maintaining traffic on the canal; nor does it include the entire cost of rearranging railroad bridges and tracks made necessary by its construction. Experienced engineers have estimated that the total cost would be about 281 million dollars.

The principal purpose of the canal would be the transportation, in barges, of ore from Lake Erie and of coal from the Ohio River. This tonnage is now carried by the railroads and would be diverted from them. One effect that would result would be an impairment of the flexibility of operations on the Great Lakes, and of the service of the railroads.

It is inconceivable that the railroads could afford to maintain all of the transhipping docks now in existence. Those at Ashtabula Harbor and Fairport Harbor, Ohio, would almost certainly be abandoned, because of the diversion of tonnage to the canal. In the opinion of experienced railroad men in positions to judge accurately, 17 ore unloaders, 3 ore docks with supporting storage, 4 coal unloaders, and possibly 1 grain elevator and 1 warehouse at Lake Erie ports would be abandoned for the same reason. With the abandonment of these facilities, the opportunity for diversion of vessels from one dock to another would be destroyed to a great extent.

Another important factor aiding in the expeditious movement of ore and coal in Lake transport is the "Ore and Coal Exchange." Mr. E. A. Burslem, Examiner, Interstate Commerce Commission, states[10] that this is:

> "* * * a central agency established and maintained by the railroads with all their individual rights as to operation, dealing with shippers, and customary practices of the individual railroads * * *. The expenses of the Exchange are borne by the railroads * * *." The Exchange is for the purpose "of providing the best possible services to lake shippers; to furnish information as to coal at the ports, in transit, and the operation of coal machines at the docks; to supervise the supply, movement, routing, and delivery of ore to the furnaces; to establish contacts between railroads, coal shippers and lake vessel owners; and to furnish such other services as would facilitate the movement of coal and ore, thereby reducing the detention of cars, increasing the car supply, and adding to the facilities of the lake traffic."

Mr. Burslem cites the following as some of the more important functions of the Exchange:

(1) To issue permits regulating the movement of the lake coal to the ports; (2) to receive reports from all docks west of Buffalo of coal at the ports and the number of cars of coal in transit and due in the ports in the following

---

[10] Proposed report in Interstate Commerce Commission Docket No. 27266.

12-hr, 24-hr, 36-hr, and 48-hr periods for each transhipper or consignee, with the number of cars in each consignment; (3) to issue daily reports showing the quantity of coal at each dock, the quantity in transit, previous day's dumping and estimated dumping for the current day; (4) to keep account of the various vessels unloading at the Lake Erie ports which are named for coal loading, and to ascertain the time the boats will be unloaded and ready to sail, so that the dock at which the vessel will receive its lake-coal cargo will be advised of the time of the vessel's probable arrival in order to get coal to the docks and not delay the loading of the vessels; and (5) to receive orders from transhippers for loading coal into vessels named by the transhippers, and to transmit such information to the docks. The Exchange keeps all interested lake-coal shippers, transhippers or consignees, and carriers informed as to the situation, daily, so that they may co-ordinate their efforts and thus effectively permit the unloading of cars and the dispatching of vessels.

Many of the vessels transporting coal from the lower Lake Erie docks come to those docks loaded with ore. Thus the speed of "turn-around" is affected by both the unloading and loading time. The provision, by the railroads, of ground storage for enormous quantities of ore makes it possible to discharge the ore cargoes even if there is not immediate demand for shipment to the furnaces. Furthermore, this ground-storage makes possible the shipment of ore to the furnaces as it is needed after the close of the Lake season.

The reduction of the average stay of iron-ore carriers at Lower Lake ports from 36 hr (in 1906) to less than 11 hr (in 1937), mentioned by the author, is largely due to the capacity and efficiency of the docks owned by the railroads, the efficient service of the railroads themselves. and the service of the Ore and Coal Exchange, maintained by and at the expense of the railroads.

The writer objects to the implication which might arise from the comparison of Lake rates and rail rates on ore, given by the author. The statement is made that the "water haul" is $0.98 per gross ton from port to port as against $1.96 for the two rail hauls (that is, from the mines to the Lake and from the Lake to destination) for ore delivered at Pittsburgh and $1.63 for ore delivered at Youngstown (see heading, "Freight and Passenger Traffic: Ore"). The inference might be drawn that rail rates were excessive. Such a comparison is scarcely fair.

The author states (see "Cost and Savings") that the total expenditures for new work by the War Department on the channels, canals, and harbors of the Great Lakes to June 30, 1937, were $193 573 686.83. In addition to this, the report of the Chief of Engineers, U. S. Army, for 1937, lists an expenditure of $66 940 948 for maintenance and of $174 061 "not distributed"—a total of $67 115 009 for the five Lake engineer districts (that is, Chicago, Milwaukee, Duluth, Detroit, and Buffalo) to the same date. Thus the total expenditure amounts to $260 688 696, making an annual interest charge, at 5%, of $13 034 435. During the decade 1926 to 1935 the average annual commerce of the United States Great Lake ports is stated by the author to have been 114 837 300 short tons (see "Freight and Passenger Traffic"). The resulting cost amounts to $0.114 per short ton.

Reducing the charges per gross ton given by the author to terms of short tons, and adding to the water haul the cost (borne by the taxpayers) per short ton resulting from Government expenditures, gives the following:

Water haul charges	$0.875	
Interest on Government expenditures	0.114	
Total		$0.989
Rail Haul Charges:		
Mines to Lake ports		0.741
Lake ports to Pittsburgh		1.027
Lake ports to Youngstown		0.732

It may be assumed that the sums reported as spent for new work and for maintenance are actual costs, without any addition for interest. Had interest been added to actual expenditures from year to year and the resulting totals carried forward to show the total cost to any given date, the charges would be vastly increased.

There should also be added the costs to the Government incurred by the U. S. Lake Survey, the U. S. Bureau of Lighthouses, the U. S. Coast Guard, and by the U. S. Weather Bureau in its operation of storm-warning stations and forecasts for the Lakes region, especially applicable to navigation. These services are all mentioned by the author, but without including any costs.

It is the opinion of the writer that it is scarcely proper to combine the two rail hauls; that is, from the mines to the Lakes and from the Lakes to destination in the manner done by the author. These two steps are performed under very dissimilar conditions.

The Board of Engineers, cited previously,[8] called particular attention to the contribution of railroads in the rapid development of the various ore ranges (or mines). A special type of carrier was developed in order to handle ore from mine to vessel economically and with the greatest dispatch. The fact that there is a wide divergence in the chemical constituents of ores makes sampling and mixing necessary in order to create a certain grade. Furthermore, the ore vessels must be loaded promptly with a fixed tonnage, the chemical content to be always within a small fraction of 1% of the analysis on which it was sold. All of these factors, according to the Board, "do not allow much flexibility in the rail transportation of ore."

The special equipment provided, and the complexity of movement from the mines to vessel, mean additional expense, which must be taken into consideration in any comparison of rail rates. The movement of ore from the lower Lake Erie ports to the mills is less complicated. Special equipment is not required, but the movement is through a more congested district, and requires close supervision by the railroads to insure prompt delivery to the mills.

The operations of blast furnaces require specific mixes of ore which must be met by shipment of the grades of ore as needed. Many of the mills have little or no storage space and must depend upon incoming shipments to meet day-to-day requirements. Frequently it happens that emergency movements of ore must be made by the railroads to meet the demands of the mills.

The maintenance and operation of the facilities required for the movement of a cargo from Lake Erie to its destination are all items of expense in addition to the "line haul cost" itself, but they are included in the rate charged. On the other hand, the vessel movement from port to port is a comparatively simple one. Once the cargo is loaded, the vessel makes a continuous voyage to its destination, carrying, in some instances, nearly 15 000 gross tons of ore. For the years 1928 to 1936, inclusive, the average cargo was 9 331 tons, and the average maximum cargo 13 489 tons.

Data are not available to the writer to show the total expenditures by the railroads in providing transhipping facilities. However, the report of Mr. Burslem[9] shows an Interstate Commerce Commission valuation of the coal-loading facilities alone, as of December 31, 1935, with depreciation allowed, amounting to more than $13 000 000. To this sum should be added the value of the ore-unloading facilities, of the ore-storage areas, and of the supporting yards for both ore and coal.

The writer does not take any issue with the "Conclusion" stated by the author. He merely wishes to emphasize the part played by the railroads in the development of Lake transportation, to indicate certain "hidden costs" and to anticipate any erroneous conclusion that might be drawn as to relative costs to the public of Lake or rail transportation.

L. C. SABIN,[11] M. AM. SOC. C. E. (by letter).—The co-ordination of effort by the United States, the shipping interests, and the railroads to build up a most efficient system is emphasized in this paper. Not since the Annual Presidential Address[12] of the late Alfred Noble, Past-President, Am. Soc. C. E., in 1903 has the subject been covered with such thoroughness and understanding. Little comment remains to be made, and that only to emphasize some details regarding the extent and value of the system.

The author defines the value of water transportation in times of emergency. Even in the French and Indian Wars and in the struggle of 1812, before any improvements had been made, the waterway served a military purpose. In the Civil War the supplies for armament were made available by water service, whereas in the World War a stoppage of the flow of commerce on the Great Lakes, involving food as well as raw materials for munitions, would have been most serious. The comparative isolation now enjoyed by the system is not without its value as a feature of defense in future possible emergency.

Bearing in mind the contribution of this system of transport, attention may be called to the fact that the expenditure of the United States in improving channels and harbors—less than 200 million dollars—is equal to the cost of only three battleships; and, while it is held in readiness during peace time, for service in emergency, the system is returning annually in savings the full cost of the development.

The author mentions the practice, followed in channel improvement, of keeping the up-bound and down-bound channels separate wherever possible.

---

[11] Vice-Pres., Lake Carriers' Assoc., Cleveland, Ohio.

[12] *Transactions*, Am. Soc. C. E., Vol. L, June (1903), p. 327.

A similar system is in effect in the open lakes where on Lakes Superior, Michigan, and Huron the Lake Carriers' Association has designated separate lanes for up-bound and down-bound traffic. Adherence to these lanes is general on the part of Lake Carriers' ships, and many others follow them habitually. Their use has resulted in greatly reducing the chances of collision.

The lengths of the sailing courses from Duluth and Chicago to Buffalo are 986 miles and 893 miles, respectively. Deep-water navigation extends to Ogdensburg, N. Y., and Prescott, Ont., Canada, on the St. Lawrence River, adding 230 miles to these distances. The improved reaches in the connecting channels total about 139 miles in length.

Readiness of the ship operators to co-operate with the United States is shown by the fact that, as the improvements progressed, vessels were built to take full advantage of the better facilities. Prior to the opening of the Poe Lock in 1896 there were no cargoes exceeding 5 000 tons. Nine years later there were 191 vessels that carried more than 5 000 tons, and cargoes of 12 000 tons were being carried. Prior to the opening of the Davis Lock about 14 000 tons was the maximum cargo, whereas subsequently, cargoes of 17 000 tons were carried.

The U. S. Lighthouse Service has contributed generously to the safety of navigation. More than 900 lighted aids and more than 200 fog signals are maintained. There are also in operation 41 radio-beacon stations at important points, and all vessels enrolled in the Lake Carriers' Association are equipped with radio direction finders, the most important recent contribution to safe navigation.

Radio telephones are in use on 80 United States vessels and 50 of Canadian register. These have proved so satisfactory as a means of communication from ship to shore and ship to ship that their general use seems only a matter of time. The U. S. Lighthouse Service in co-operation with the U. S. Weather Bureau, U. S. Coast Guard, and U. S. Hydrographic Office broadcasts information regarding weather and other matters affecting navigation; and the U. S. Coast Guard Service contemplates full co-operation through supplying radio equipment to a large number of life-saving stations on shore.

In the further interest of safe navigation load lines are marked on all ships limiting the depth to which they may be submerged. In channels of limited depth current drafts are recommended by the Lake Carriers' Association according to the progress of dredging and the prevailing water level.

Among the ports on the Great Lakes there are 18 having an annual traffic in excess of 3 million tons. On the Atlantic Coast there are 13 such harbors, and 7 on the Pacific. The net total United States Commerce of the Great Lakes, excluding that pertaining only to Canada, has averaged 117 million tons annually for the ten years 1928–1937. The foreign commerce of all ocean and gulf ports for the same period averaged 81 million tons. When computed in ton-miles of movement the traffic is still more impressive. In 1936 the ton-mileage on the Lakes was 77 billion, whereas that of all other inland waterways was 15 billion. Another view of the volume of traffic may be gained by the statement that during the seasons of navigation covered by the six years from 1924 to 1929 ships passed Detroit on the average of once every 12 min with an average cargo of 3 300 tons.

Freight rates are given for ore and coal. Reduced to net tons the cost of ore transport, exclusive of terminal charges, is 71.4 cents per ton. The length of haul varies from 280 miles (a small tonnage from Escanaba to the south end of Lake Michigan) to 986 miles (Duluth to Buffalo) with an average of about 800 miles. The ton-mile rate is thus about 0.9 mill.

On coal from Lake Erie to Duluth the rate is 45 cents per net ton for 800 miles, which gives a ton-mile rate of 0.56 mill. The rate to Milwaukee on Lake Michigan is 55 cents (a trifle higher than Lake Erie to Duluth because of lack of return loads), giving a ton-mile rate of about 0.65 mill. Shorter hauls from Lake Erie to near-by ports carry a higher ton-mile rate. The combined rates on 87 million tons passing St. Marys Falls Canal in 1937, including package freight, is given as 1.07 mills per ton-mile. This low cost of transportation is not found in any other large transportation system.

TESTS ON BUILT-UP COLUMNS OF STRUCTURAL ALUMINUM ALLOYS

BY MARSHALL HOLT,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. ALFRED S. NILES, AND MARSHALL HOLT.

SYNOPSIS

Results from tests on fifteen built-up column specimens of structural aluminum alloys and on two of structural steel are presented in this paper. The investigation was a study of the effect of the shape of section on the strength of built-up columns. All specimens had maximum slenderness ratios of about 40 and cross-section areas of 7 or 8 sq in. Strains and deflections were measured under various loading conditions. In the range of working loads the shape of the cross-section has no significant effect on the ratio of the measured to computed deflections of the axis of the specimen nor on the magnitude of the transverse shear indicated by the lacing-bar stresses. The shape of the cross-section has a significant effect on the ratio of the measured to computed stresses, the local deflections under higher loads, and on the type of failure, whether by buckling of a component part or by bending as a unit. Short built-up columns of high-strength aluminum alloys are likely to fail by local buckling at average stresses less than the yield strength of the material when the width-to-thickness ratio of outstanding plates and legs of angles exceeds about 12 and when the width-to-thickness ratio of the cover-plates exceeds about 40.

INTRODUCTION

Structural designers are always confronted with the problem of determining the strength of compression members. These members may be single units (structural shapes), or they may be built-up of a number of such shapes. Considerable work, both analytical and experimental, has been done in the study of the strength of columns. It has been established that the strength of the member as a column is affected by its stiffness and the compactness of the cross-section, as well as by the strength of the material. Columns acted upon by axially applied loads might fail at stresses considerably less than the

---

NOTE.—Published in November, 1938, *Proceedings*.

[1] Research Engr., Aluminum Research Laboratories, New Kensington, Pa.

yield strength of the material by sidewise bending because of lateral instability of the member as a whole, or by twisting or buckling of a component part because the parts themselves are not sufficiently rigid. The solution of the problem then lies in knowing not only the fundamental behavior of columns, but also the effects of the shape and proportions of the cross-section of the column upon its compressive strength.

The results of many tests on steel columns can be found in the technical literature. These test results form the basis for specification requirements. The tests discussed in this paper were made as part of a research program to acquire information for the establishment of a set of specifications for the structural use of the high-strength aluminum alloys.

Notation.—The letter symbols used in this paper are defined where they first appear and are assembled for reference in the Appendix.

DESCRIPTION OF SPECIMENS

Fifteen of the seventeen specimens used in this investigation were fabricated of high-strength aluminum alloys having mechanical properties comparable with those of mild steel. The other two specimens were of structural steel and duplicated two of the aluminum alloy specimens in size and shape of the cross-section. Each of the specimens had a greatest slenderness ratio of about 40 and an area of 7 or 8 sq in.

Table 1 contains a description of the specimens. Each piece of material was given a number (Column (8), Table 1) by means of which specimens for determining the mechanical properties of the materials were identified. The weight of the details, such as rivets, lacing-bars, and batten-plates, is the difference in the weight of the complete specimen and that of the main members before the rivet holes were punched. The length was determined after the ends had been carefully machined by turning the specimen on centers in a lathe. The gross area was calculated from the weight and length of short pieces and the nominal specific gravity of the material, 2.79 for Items Nos. 17 S and 25 S, and 7.85 for steel. The aluminum alloys were in the heat-treated condition.[2] The radii of gyration were computed on the assumption of unified action of the main members. The slenderness ratios of the specimens as a whole are given for the two principal axes, as is the slenderness ratio of the segments, which is the distance between two adjacent rivets divided by the radius of gyration of the part (see Columns (17), (18), and (19), Table 1).

In order to emphasize the effect of the shape of the cross-section and to obtain a suitable area of cross-section, the component parts used in some of these specimens are thinner than allowed by specifications commonly used in the design of structural steel.

The mechanical properties of the materials in tension are given in Table 2. The tests were made on A. S. T. M. (American Society for Testing Materials) standard tensile specimens having a rectangular section and a width of 0.5 in. The stress-strain relations of the aluminum alloys were determined with a mirror-type extensometer, using a 2-in. gage length, whereas a modified form of the bell-crank type of extensometer was used with the steel.

The mechanical properties of the materials in compression are also given in Table 2. The tests were made on short sections of the pieces having slenderness ratios of 10. The stress-strain relations were determined by measuring the relative movement of the heads of the testing machine with two dial-gages reading directly to 0.001 in.

* See Table 1. † Specimen taken parallel to direction of rolling. ‡ Specimen taken across direction of rolling. § For aluminum alloys, at 0.2% set; and, for steel, at 0.45% set. ‖ Broke through the gage point. ¶ Slenderness ratio = 10, tested with flat ends.

It should be borne in mind that the aluminum alloys, like other non-ferrous metals and some high-strength steels, do not have a definite point of yielding as does mild steel.

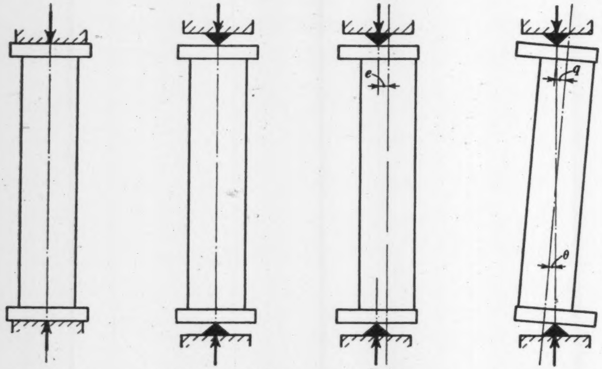
METHODS OF LOADING

The column tests were made in a testing machine of the hydraulic type, having a maximum capacity of 300 000 lb, and intermediate load-ranges. The load was applied to the ends of the specimens using the various loading conditions shown in Fig. 1.

Flat end conditions (Fig. 1(*a*)) were obtained by centering the specimen on the fixed bearing heads of the testing machine.

Round end conditions (Fig. 1(*b*)) were produced with knife-edge bearing blocks consisting of a bearing plate supported by a single knife-edge. The specimens were thus allowed to deflect freely normal to the plane of the knife-edges, but were restrained with the condition of flat ends in the plane of the knife-edges. The specimens were carefully centered in an attempt to make the axis of the specimen coincide with the plane of the knife-edges.

Eccentric loadings (Fig. 1(*c*)) were produced with the knife-edge bearings by placing the specimen off center the same distance at each end and in the same direction. The eccentricity, *e*, is defined as the distance between the axis of the column and the plane of the knife-edges. The values of the eccentricity ratio, $\frac{e\,c}{k^2}$, were between about 0.4 and 0.6. In computing these values of eccentricity ratio, the value of *c*, distance from the neutral axis to the point where the stress is desired, was taken as the distance to the extreme fiber and *k* is the corresponding radius of gyration.



(*a*) FLAT ENDS (*b*) ROUND ENDS (Knife Edges) (*c*) ECCENTRIC LOAD (*d*) OBLIQUE LOAD

Fig. 1.—End Conditions for Loading Columns

Oblique loadings (Fig. 1(*d*)) were produced with the knife-edge bearings by placing the specimen off center the same distance at each end, but in opposite directions at the two ends. The obliquity, *q*, is defined as the distance between the axis of the column at the ends and the plane of the knife-edges. The values of the obliquity ratio, $\frac{q\,c}{k^2}$, were between about 0.4 and 0.6

Some tests were made with the specimen off center each way from the plane of the knife-edges. In some cases, the knife-edges were parallel, in turn, to the two principal axes of the cross-section of the specimen. All specimens were loaded to failure with the condition of flat ends, as shown in Fig. 1(*a*).

MEASUREMENTS FOR STRAIN AND DEFLECTION

Strains were measured on several gage lines on the main members using a 2-in. strain-gage. The lines were placed to show the distribution of stress (strain) in the members not only around the section but also along the length of the specimen. Tensometers (1-in. gage length) were used in measuring strains on both sides of the lacing-bars and on rosettes (gage lines intersecting at a point) on batten and cover-plates.

Deflections at the center of the specimens were measured by the use of fine wires, stretched between pins at the ends of the specimens, and scales (graduated to $\frac{1}{50}$ in.) mounted on mirrors which, in turn, were mounted on the specimen. In addition to the measurements at the center, the deflections in the direction of bending were measured at the quarter-points in some of the tests using eccentric and oblique loadings.

Discussion of Test Data

The measured strains were interpreted into stresses using values of modulus of elasticity of 10 300 000 lb per sq in. for the aluminum alloys and 29 000 000 lb per sq in. for steel. Only a very small part of all the data accumulated in these tests are presented herein. Fig. 2 gives the load-deflection data from the flat end tests; Fig. 3 gives typical eccentricity-deflection data from the eccentric load tests; and Fig. 4 gives typical transverse shear-obliquity data from the oblique load tests. The curves indicated by the stress in Bars 20 and 32 are shown as broken lines, and the curve indicated by the stress in all bars is shown solid.

Measured Stresses

In general, the measured stresses are slightly lower than the computed values obtained by the following equations:

For axial loads,

$$s = \frac{P}{A} \qquad \text{(1a)}$$

for eccentric loads,

$$s = \frac{P}{A}\left(1 + \frac{e\,c}{k^2} \sec \frac{L}{2\,k} \sqrt{\frac{P}{A\,E}}\right) \qquad \text{(1b)}$$

and, for oblique loads,

$$s = \frac{P}{A}\left(1 + \frac{q\,c}{k^2}\right) \qquad \text{(1c)}$$

in which s = computed unit stress, in pounds per square inch; P = total load, in pounds; A = cross-section area of main members, in square inches; E = the modulus of elasticity of the material, in pounds per square inch; and L = length, in inches. The agreement was improved when added precautions were taken to avoid the effects of temperature variations on the measured strains.

For the case of low axial loads, there seems to be no significant tendency for any one general type of specimen to have a more uniform distribution of stress than any other type. For higher loads, however, there is a decided tendency for the specimens with thin outstanding plates to have a pronounced variation in the stress distribution. These same remarks can be made for the cases of eccentric and oblique loads when considering the variation of stresses on gage lines the same distance from the neutral axis.

For the case of axial loads, there is no significant variation of stress at the various sections along the length of the member. With eccentric loads the larger stresses are found, of course, on the same side of the specimen at all sections and the variation along the length of the specimen is not great. With

oblique loads there is a systematic variation of stress along the length of the member. At one end the greater stresses are on one side of the section and at the other end the greater stresses are on the other side. The stresses at the center section are fairly uniformly distributed.

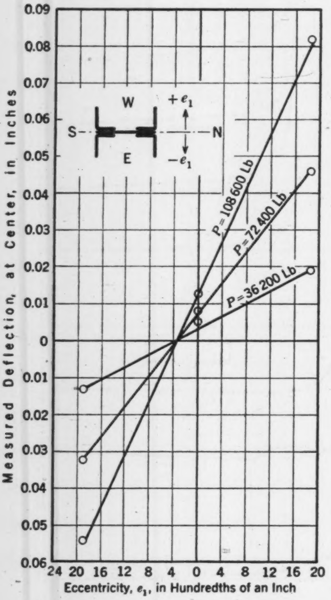

Fig. 3.—Relation Between Deflection and Eccentricity, e_1, Specimen 4A1P-1

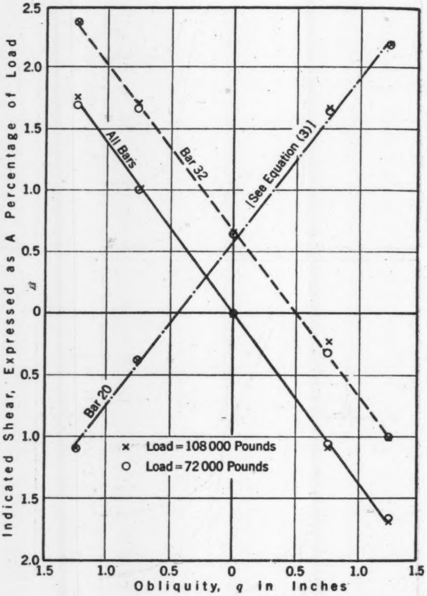

Fig. 4.—Transverse Shear Indicated by the Measured Stresses in Lacing-Bar (2C-2)

Deflections with Flat-End Conditions

The relations between the load and the measured deflections at the center, when the specimens were tested as columns with flat ends, are shown in Fig. 2. These curves show that the twisting of the specimen or the bending of an outstanding part was more significant, in many cases, than the deflection of the axis of the specimen. It was noted that the shape of the edge of the outstanding plate of Specimen 2A1P-1 changed from double curvature (**S**-curve) to single curvature (**C**-curve) at a load of about 95 000 lb. This change in shape was accompanied by noticeable twisting. Specimen 2A1P-2 showed this same type of action. It is reasonable to believe that the deflections of the outstanding legs of the angles of Specimen 2A1P-3 produced a condition of instability that influenced the strength of the member. The twisting of the pairs of angles of Specimen 4A-2 is probably responsible for the change in the direction of bending of the axis of the specimen; that is, the twisting introduced eccentricities of loading with effects opposite to those of the initial "accidental" eccentricity.

("Accidental eccentricity" is defined as the unintentional eccentricity that must have occurred, including the effects of crookedness of the member, fabrication defects, etc., as well as the error in the location of the point of application of the load.) Specimen 2C-3 also gave a queer curve for the deflections of the north and south sides, which was probably produced by erratic action of the lacing-bar joints. The sudden breaks in the curves of Specimen 2C1P-2 are probably a result of the buckling of the plate.

Analyses of load-deflection data have been developed by Professors W. Ayrton and John Perry,[3] and by Professor R. V. Southwell,[4] by which the eccentricity of loading and the critical column strength of the specimen can be determined. It is then possible to determine the fixation of the ends of the specimen from the critical column strength and the Euler formula for column strengths. There are only a few of these specimens in which the action of the component parts was sufficiently unified and free from twisting that such analyses might have been applied to the data.

Values of accidental eccentricity can be obtained from these data as the eccentricity required to give a good agreement between the measured and computed values of deflection. Such values of accidental eccentricity are not reliable because the measured deflections were greatly influenced by the lack of integral action of the specimen. They would be the upper limiting value of the accidental eccentricity, however. Such values have been used subsequently herein in computing the strength of the members (see heading, "Computed Column Action and Tests to Failure").

The specimens with lacing and relatively light tie-plates show a tendency toward large values of the eccentricity ratio, $\frac{e\,c}{k^2}$, resulting from accidental eccentricities. For the other specimens, the shape of the section seems to have no significant effect on the values of eccentricity ratio resulting from the accidental eccentricity.

DEFLECTION UNDER ECCENTRIC LOADS

The averages of the measured deflections for positive and negative eccentricities agree quite satisfactorily with computed values obtained by the secant formula for deflection:

$$y = e\left(\sec \frac{L}{2\,k}\sqrt{\frac{P}{A\,E}} - 1\right) \dots\dots\dots\dots\dots\dots (2)$$

In some cases the measured deflection for positive eccentricity is quite different from the value for negative eccentricity. These differences are produced by accidental eccentricities of loading, the magnitude of which can be obtained from curves showing the relation between the deflection and the intentional eccentricity. In Fig. 3, which shows a typical eccentricity-deflection relation, the accidental eccentricity is that which corresponds to zero measured deflection.

The relations of the measured and computed deflections of the axes of the specimens do not seem to be influenced by the shape of the section. There were a few cases in which the local bending of the component parts was noticeable. These local deflections were influenced by the shape of the section; for example, in the two T-shaped specimens (2A1P-1 and 2A1P-2), the measured values show that the deflection was accompanied by twisting about a longitudinal axis. This action was observed even for small loads.

Deflections Under Oblique Loads

In general, the deflections measured at the quarter-points were small. Percentage variations from the computed values are quite large in some cases but the differences between the measured and computed values for the aluminum alloy specimens are, in only one case, greater than 0.008 in. for average stresses of 10 000 lb per sq in. This case is the two-angle, star-shaped specimen (2A-1) for the condition in which the axis of bending is across the tie-plates. Otherwise, the shape of the section seemed to have no significant effect on the relation of the measured and computed deflections of the axes of the specimens. In this case (Specimen 2A-1), the average of the measured values is about 2.5 times as great as the computed value.

The computed values used in these comparisons were obtained as one-eighth the value computed by Equation (2) for the specimen loaded with an eccentricity equal in magnitude to the obliquity. Although this formula does not strictly apply to this type of loading, the error introduced is quite small.

The twisting of the T-shaped specimens was again noticeable even for the low loads and did not change direction with a reversal in the direction of the obliquity.

Lacing-Bar Stresses and Shears

It was found early in the investigation that because of the bending it was necessary to measure the stresses on both faces of the lacing-bars in order to arrive at a satisfactory value of the load on the bar. In some cases the maximum stress in a lacing-bar was more than three times the average stress. With the specimens tested with the condition of flat ends or with eccentric loads, the stresses in the lacing-bars were rather small (less than 4 800 lb per sq in. for average stresses, $\frac{P}{A}$, of 15 000 lb per sq in.). The transverse shears indicated by the average of the lacing-bar stresses were equal to not more than two-thirds of 1% of the total longitudinal load. The transverse shear indicated by the most highly stressed lacing-bar (Specimen 2C-1) was equal to about 1% of the load when the specimen was tested as a column with flat ends. These indicated transverse shears were arrived at as the transverse load required to produce the measured average stress in the lacing-bars, assuming that the bars support all the shear.

With the specimens tested with oblique loads, the stresses in the lacing-bars are somewhat larger and indicate values of transverse shear (based on the average stresses for all the bars of a specimen) as high as 3.9% of the longitudinal load. The typical data in Fig. 4 show the relation between the indicated shear and the ratio of obliquity to the length of the specimen. It should be noticed that the indicated shear, expressed as a percentage of the total load, is independent of the load and can be represented by an empirical equation of the form,

$$V_i = F + G\left(\frac{2q}{100L}\right) \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

The data indicate the maximum values of the constants, F and G, to be 0.7 and 1.7, respectively. It is shown in Fig. 4 that the relation between the indicated shear and the obliquity is a straight line, and that for individual lacing-bars there is some indicated shear even for zero intentional obliquity.

The average stresses in the lacing of the specimens with heavy batten-plates at the ends (4A-1 and 4A-2) indicate transverse shears between one-third and two-thirds of the transverse component of the load. The specimens with lighter batten-plates at the ends have an indicated shear between 0.8 and 1.7 times the transverse component of the load. The average stresses in the lacing of the specimens with one cover-plate and one plane of lacing indicate a transverse shear on the lacing equal to about one-fourth the transverse component of the load.

Some of the equations commonly used for estimating the shear in built-up columns follow from analyses of the shape of the deflected structure. In generalizing and reducing the formulas, the value of the modulus of elasticity is taken as the initial modulus and the value of the average stress is taken as the ultimate strength of the member.[5] For use with structural steel (which has a very definite yield strength) this combination of values might be acceptable, but with the high-strength steels and non-ferrous metals which do not have such a definite point of yielding this is subject to criticism. An effective modulus of elasticity for strengths above the elastic stress range might be used in the generalization but the resulting formulas would be complicated considerably.

Other equations in common use are based on analyses that consider the column as a beam and the shear load producing a bending stress equal to the reduction in strength given by the slenderness-ratio term of the straight line or Rankine formulas.[6] When used to estimate the shear at failure, these analyses are subject to the foregoing criticism.

The data obtained on these specimens indicate that, for average stresses within the elastic range, the transverse shear on axially loaded columns is a constant percentage of the load on the specimen. In the case of Specimen 2C-1 (with the highest indicated shear), the transverse shear at failure would be about 2 350 lb if the relation between shear and axial load were the same (1%) at failure as at working stresses. The average stress in the most highly stressed lacing-bar would be 4 930 lb per sq in., whereas the Euler column strength of the bars is 7 400 lb per sq in. Since the failure of the specimen (described subsequently) was accompanied by the buckling of the lacing-bars, either the shear was greater than 1% of the load or the bar was in effect an eccentrically loaded column. Either explanation is tenable. This shear of 2 350 lb represents a transverse load of 330 lb per sq in. of cross-section of the main members. Although the results of this investigation do not definitely establish a value for the transverse load, they indicate that the value of 600 lb per sq in. of cross-section used in the old A. R. E. A. (American Railway Engineering Association) specifications for pin-ended columns is quite reasonable. These test data also indicate that the shear on eccentrically loaded columns should be taken greater than 1%, the amount depending on the value of the eccentricity ratio, $\frac{e\,c}{k^2}$.

FORMULAS FOR PREDICTING COLUMN STRENGTHS

Before proceeding with the discussion of the tests, a few remarks will be interjected concerning formulas for predicting the column strength and the type of failure that might be expected.

The straight-line type formula is commonly used for predicting the strength of columns that fail by the sidewise bending of the member as a unit. This equation is of the form,

$$\frac{P}{A} = s_0 - C\frac{K\,L}{k} \qquad \text{(4)}$$

in which s_0 = column strength, in pounds per square inch, corresponding to zero slenderness ratio. The range of slenderness ratios is limited for which this equation is applicable; but the value of C can be chosen so that the combination of this equation with the Euler column formula covers the full range of slenderness ratios. This combination of formulas has been found applicable to the various aluminum alloys.[7]

Equations for stresses in columns, such as Equation (1*b*) and that of Professors Ayrton and Perry,[8]

$$s = \frac{P}{A}\left(1 + \frac{P'}{P' - P}\,\frac{e\,c}{k^2}\right) \qquad \text{(5)}$$

can be used also for predicting the ultimate strength of columns that fail by sidewise bending as a unit. The value of s in these equations is set equal to the compressive strength of the material and a value of Load P is determined that satisfies the equation. The solution is usually most easily obtained by trial. It will be noticed that the value of the modulus of elasticity enters each of these equations, appearing indirectly in Equation (5). This presents no particular problem in the case of structural steel, which has a definite yield strength; but for some of the high-strength steels and non-ferrous metals the evaluation of an effective modulus of elasticity [9] must be made.

Although Equations (1*b*), (4), and (5) can be used to predict the ultimate strength of a column that fails by sidewise bending of the member as a unit, if the member is subject to failure by local buckling or twisting, it must be treated as a local instability problem. Naturally, the strength of the member will be limited by the lowest of the strengths predicted by a consideration of all the types of failure that might occur. Equations have been derived for some special cases of local buckling.

[8] "On Struts," by W. Ayrton and John Perry, *The Engineer* (London), December 10 and 24, 1886, Vol. 62, Equation (22); also "Rational Design of Steel Columns," by D. H. Young, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 422.

[9] "Rational Design of Steel Columns," by D. H. Young, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 467.

For the case of wide thin plates, the critical stress, s_{cr}, at which buckling occurs, can be computed by the equation:[10]

$$s_{cr} = \frac{a\,E}{1 - \mu^2}\left(\frac{t}{b}\right)^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

in which a = a coefficient that depends on the proportions of the plate and the type of restraint along the edges of the plate; μ = Poisson's ratio; t = thickness; and b = width of plate. Values of Coefficient a for various loading conditions and various conditions of the edges of the plate can be obtained from the reference giving the equation. It should be borne in mind that this value of s_{cr} is the maximum average stress that can be developed in the plate and at which buckling occurs. The agreement between the critical stress and the average stress at which collapse occurs will depend on the shape and proportions of the entire cross-section of the column and the loading conditions of the member; that is, in the specimens of which the plate is the principal part of the member, the agreement between the critical stress and the average stress at failure should be rather close, whereas for a specimen in which the plate is merely an appendage, the average stress at final collapse of the entire member may be considerably greater than the critical stress at which the plate buckles. The average stress at the collapse of a specimen with round or pinned ends will probably agree very well with the computed critical stress and, of course, will be less than the test result for a similar specimen with restrained or fixed ends.

Some cases of local buckling can be treated satisfactorily by using a proper value of s in Equations (1b) and (5). These formulas would include those cases in which the maximum stress, due to combined axial load and bending, is developed in some part that is subject to local buckling. The value of s then is the compressive strength of that part and can probably be determined most satisfactorily by a compression test on a short length of the part.

COMPUTED COLUMN ACTION AND TESTS TO FAILURE

The computed strengths of the specimens and the types of failure to be expected are given in Table 3. In Column (2), the larger of the two numbers corresponds to the fixed-edge condition and the smaller to the simply supported edge condition. In Column (4), Table 3, two values are listed for Specimens 2C-1 and 2C-2. The first value corresponds to the case of bending about the axis of least computed stiffness and the second to the case of bending about the axis of greatest computed stiffness. The difference in the values of accidental eccentricity for the two directions makes this investigation of strength necessary. In calculations involving stresses above the elastic range, an effective modulus of elasticity has been used. The effective modulus was assumed to

decrease along a straight line from the initial value at the upper limit of the elastic range to the value of the tangent modulus at the yield strength (0.2% set) and from this decreased value along another straight line to zero at the maximum stress.

The column strength of the member acting as a unit was obtained by the straight-line formula, Equation (4), based on the properties of the material in the specimen and also by Equation (5), using a value of accidental eccentricity consistent with the data in Fig. 2. In these computations, the value of K was taken equal to 0.5 which assumes that the specimens acted as columns with fixed ends. For each specimen the critical strength based on the local buckling of the plates was obtained by Equation (6) using values of the coefficient corresponding to two widely different conditions of edge support, namely, simply supported edges and fixed edges. The actual edge conditions usually provide some restraint, so the critical strength that can reasonably be expected can be obtained by interpolation between these extreme values. The predicted type of failure is that corresponding to the lowest computed strength, whether by local buckling or by bending as a unit. The maximum loads and column strengths are for these specimens tested as columns with flat ends. In nearly all cases the type of failure was predicted correctly. In a few cases the failure appears to be a combination of buckling and bending or of buckling of more than one part.

The strength of Specimen 2A-1 was computed on the basis of simple support along the back of the plate. This seems reasonable because the four outstanding legs are all equally subject to buckling with the resultant twists centering about the shear centers of the individual angles. This reasoning does not apply to Specimen 4A-3 (Fig. 5), because, although the four legs are all equally subject to buckling, the resultant twist must center about the heels of the individual angles. Thus, the angles are stronger than similar angles, free to twist about their own shear centers. The outstanding plates of the other specimens are all restrained to a certain extent. The two values of computed critical stress given in Table 3 are based on the two conditions of the back edge of the plate mentioned previously. For those specimens with computed strengths in the plastic range the effect of the restraint at the edge of the plate is not so pronounced as in the cases in which the strength is in the elastic range. This results from the fact that the effective modulus of elasticity varies with the stress.

A study of the load-deflection curve and the stresses measured at the free edge of the plate of Specimen 2A1P-1 indicates that the value of computed critical stress corresponding to fixed edges is close to the average stress at which buckling occurred, whereas a similar study for Specimen 2A1P-2 (Fig. 5), indicates that the value corresponding to fixed edges is much too great. The differences between the ultimate strengths and these computed critical strengths should not be surprising in view of the definitions of terms and the previous discussion of Equation (6). The ultimate strength of Specimen 2A1P-4 (Fig. 5) was probably reduced somewhat by the buckling of the plate.

The critical strength of Specimen 4A-2 is computed for the outstanding (short) legs of the angles with a ratio of width to thickness of 12 and a large ratio of length to width. It is also computed for the inside (long) legs with a ratio of width to thickness of 16 and a length equal to the width. The range of values based on both simple and built-in support at the back edge of the plate is from 27 000 lb per sq in. to 30 900 lb per sq in. The reversal of the load-deflection curve in Fig. 2(*a*) at a stress of about 26 000 lb per sq in., is probably associated with the buckling of the legs of the angles. The ultimate strength is 32 230 lb per sq in.

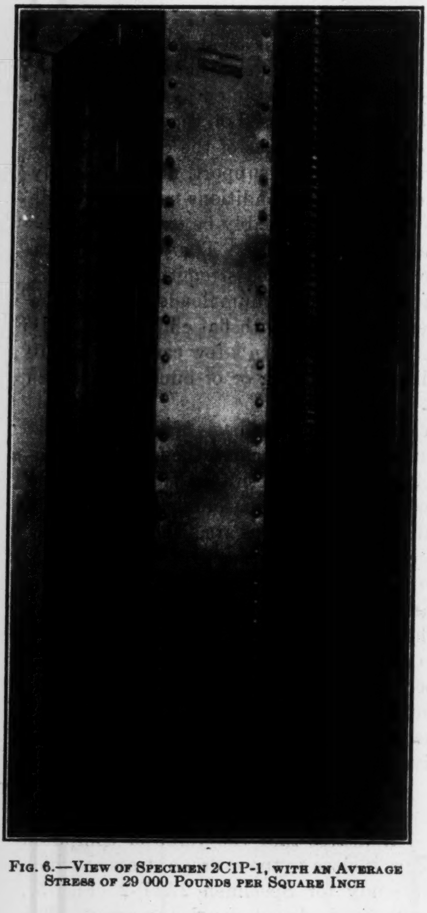

Fig. 6.—View of Specimen 2C1P-1, with an Average Stress of 29 000 Pounds per Square Inch

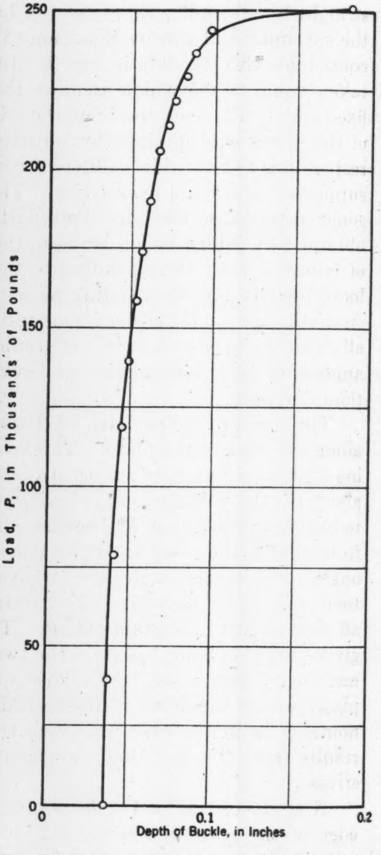

Fig. 7.—Relation Between the Load and the Depth of Buckle, in Plate of Specimen 2C1P-2

Specimens 4A-3, 4A1P-1, and 4A1P-2 (Fig. 5), with outstanding legs of angles, having width-to-thickness ratios of 8, 12, and 10, respectively, developed strengths equal to the values computed by the straight-line formula and by

Equation (5). Specimen 4A-2 (Fig. 5) developed 98% of the strength predicted by the straight-line formula, and Specimens 2A1P-1 and 2A1P-2 developed only about 60% of the strength similarly computed. These comparisons should emphasize the fact that short columns with outstanding plates having ratios of width to thickness greater than about 12 are subject to local failure at loads less than those predicted by the usual column formulas.

Specimens 2C-1 and 2C-3 (Fig. 5) can scarcely be said to act as units in view of the fact that failure occurred by bending about the axis of greatest computed stiffness. The ratio of moments of inertia is 1 : 1.3. The failure of Specimen 2C-3 (Fig. 5) was accompanied by the formation of Lueders' lines. The agreement between the test results and the computed values was very good.

Fig. 6 shows Specimen 2C1P-1 under an average stress of 29 000 lb per sq in. The buckling of the plate is quite apparent although at an average stress of 28 000 lb per sq in., the plate appeared smooth. These values agree fairly well with the critical strength computed on the basis that the edges of the plate are built in and the width is the clear distance between the rows of rivets.

Fig. 7 shows the relation between the load and the depth of a buckle in the plate of Specimen 2C1P-2. The plate buckled rather suddenly at a load of 205 000 lb. This load coincides with that at which the "break" occurred in the load-deflection curve of Fig. 2(*j*). Besides the formation of this buckle, failure was accompanied by the formation of Lueders' lines. The computed strengths for this specimen given in Table 3 are about equal to the yield strength of the material. The test result is about 10% less than this, probably as a result of the initial unevenness of the plate.

The computed critical strength of Specimen 2C2P-1 agrees fairly well with the break in the load-deflection curve. The ultimate strength exceeds this value by 19 per cent. None of the three specimens, with a ratio of width of plate (between the lines of rivets) to thickness of about 46, developed the yield strength of the materials nor the strength predicted by the straight-line formulas.

CONCLUSIONS

The following conclusions regarding built-up columns of high-strength aluminum alloys are justified by the foregoing data and discussion:

(1) For low loads the shape of the cross-section has no significant effect on the distribution of stress; but for the higher loads the specimens with thin outstanding plates have a pronounced variation in the stress;

(2) The shape and proportions of the cross-section have a significant effect on the ultimate strength and the type of failure, whether by bending as a unit or by local buckling;

(3) The type of failure, whether by local buckling of a component part or by bending as a unit, can be predicted as the type of failure corresponding to the least of the strengths computed by the various equations for critical stress and column strength;

(4) In order to avoid failure of short columns $\left(\frac{L}{k} = \text{about } 40\right)$ by local buckling at a load less than that predicted for the column acting as a unit, the

width-to-thickness ratio of outstanding plates and legs of angles should not exceed about 12 and the ratio of width to thickness of cover-plates with a row of rivets near each edge should not exceed about 40;

(5) Local buckling will not always result in the collapse of the entire member, but may be only a wrinkling of the buckled part;

(6) In the range of working loads the shape and proportions of the cross-section have no significant effect on either the ratio of measured deflection of the axis of the member to the computed deflection or on the magnitude of the indicated shear, expressed as a percentage of the load; and,

(7) For two-channel members with two planes of lacing to develop equal column strengths in the two principal directions, the moment of inertia of the section parallel to the lacing, computed in the usual manner, should be greater than that parallel to the webs of the channels in order to counteract the minute unintentional slack in the lacing-bar joints.

APPENDIX

NOTATION

The following notation conforms essentially with American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials[11] compiled by a committee of the American Standards Association with Society representation, and approved by the Association in 1932:

A = area of cross-section, main members, in square inches;

a = a coefficient in Equation (6), that depends on the proportions of the plate and the type of restraint along the edges of the plate;

b = breadth; width of plate, in inches;

C = a coefficient chosen so that the combination of Equation (4) with the Euler formula covers the full range of slenderness ratios;

c = distance, in inches, from the neutral axis to the point where the stress is desired;

E = modulus of elasticity of the material, in pounds per square inch;

e = eccentricity of loading, in inches;

F = term in Equation (3);

G = term in Equation (3);

K = a coefficient describing the end conditions; taken as unity for a column with round ends, and as 0.5 for a column with fixed ends;

---

[11] A.S.A.—*Z*10*A*—1932.

k = radius of gyration of the cross-section, in inches, assuming unified action of the component parts of the member;

L = length, in inches;

P = total load, in pounds; P' = Euler column load, in pounds;

q = obliquity of loading, in inches; distance between the axis of the columns at the ends and the plane of the knife-edges;

s = average unit stress, in pounds per square inch = $\frac{P}{A}$; s_{cr} = critical buckling stress; s' = Euler's column strength = $\frac{\pi^2 E}{\left(\frac{K L}{k}\right)^2}$; s_0 = column strength corresponding to zero slenderness ratio;

t = thickness, in inches;

V = total shear, in pounds; V_i = indicated shear, expressed as a percentage of the total load, P;

y = deflection, in inches; and,

μ = Poisson's ratio.

DISCUSSION

Alfred S. Niles,[12] Assoc. M. Am. Soc. C. E. (by letter).—From two distinct viewpoints, Mr. Holt's paper is a valuable contribution to the literature of column design. Its most obvious merit is that it extends the knowledge of column behavior to large members of aluminum alloy. It also throws additional light on some problems of column design that are of interest to the engineer regardless of whether he intends to use aluminum alloy or steel as his structural material. The discussion of the stresses in lacing-bars, for example, should be of as great value to the designer of steel columns as to the worker with aluminum. In the past this problem has been slighted and lacing-bars have been designed by methods based on so many assumptions and on so few experimental data that they scarcely rise to the dignity of being called empirical, but can only be described as rule of thumb. The more information that can be obtained on this and several of the other topics treated in the paper, the more efficiently will the engineer be able to design his columns, and the more safely can he use unconventional sections for special purposes.

One phase of the tests that is rather meagerly covered in the paper is the tendency of the "cross" and the "tee" sections to fail by twisting. In Table 3 four columns are listed for which failure by twisting was predicted, and in each case the prediction was fulfilled. It may be noticed, however, that there is no mention of predicted loads at which failure in this manner would take place. Furthermore, it should be noted that three of these columns failed under much lower average stresses than those predicted by Equations (3) and (5). It might be thought that Equation (6) would be helpful in predicting the probable stress at failure by twisting, since buckling of an outstanding leg due to local instability would tend to cause the columns in question to twist. That this equation does not apply is evident from the fact that two of these columns failed by twisting under much higher unit stresses than the larger values obtained from that formula. The real situation is that, for any column there is a critical load which cannot be exceeded without producing general instability with respect to torsional failure. For most of the standard column sections this load is so much larger than the critical loads corresponding to other types of failure that it need not be considered in design. For the "cross" and "tee" sections, however, it is likely to be less than the other critical loads and becomes a limiting factor. This type of failure is not discussed in the paper although the aforementioned predictions show that the author was properly aware of its likelihood. Its importance to the designer is indicated by the relatively low average stresses at which the first three columns listed in Table 3 failed.

One probable reason for the lack of predictions of the stresses at which torsional failure was to be expected is the present very primitive state of the theory applicable to this phenomenon. Although it had been noticed in a number of earlier column tests it was not until quite recently that any notable progress was made in explaining it rationally or in predicting the loads at which it might be expected to occur. At present the best discussion of the phenomenon easily available to American engineers is a report by E. E. Lundquist, Jun. Am. Soc. C. E., and Mr. C. M. Fligg[13] of the engineering staff of the National Advisory Committee for Aeronautics. The theory of this report, however, is incomplete since it is limited to the case of a column with a doubly symmetrical cross-section, and is not supported by test data.

MARSHALL HOLT,[14] ASSOC. M. AM. SOC. C. E. (by letter).—The writer wishes to thank Professor Niles for his discussion of this paper. As stated, a theory for columns that fail by twisting, and reliable equations for computing the strength of such columns, are not readily available. When satisfactory methods become available for predicting the strength of members that fail in this manner, the use of such members in special locations may become more common.

The prediction of twisting failure for four of the specimens in Table 3 was based on the following reasoning: The outstanding plates would fail by local buckling because the strength for this mode of failure is less than the strength if failure were to occur by lateral deflection of the specimen as a unit (compare the computed strength obtained by Equation (6) with the strengths obtained by Equations (4) and (5)). If the supported edge of the plate were free to rotate (but not deflect), the free edge of the plate would buckle into a single wave; but if the supported edge were fixed against rotation, the free edge would deflect into a number of waves, the number depending on the relative proportions of the plate. Since the torsional rigidity of these specimens is so small, the degree of fixation at the supported edge of the outstanding plate would not cause the development of more than one wave in the free edge. Thus, the center of the specimen would merely twist relative to the ends.

Failure under this type of action may or may not result in the collapse of the specimen but occurs at that load at which the lateral deflection of the free edge of the outstanding parts increases at a rapidly increasing rate (see Figs. 2(*m*) and 2(*n*)). The maximum load sustained by the specimen may be greatly in excess of this buckling load and, of course, will be accompanied by collapse of the specimen. There seems to be no method available for predicting the spread between the buckling load and the maximum load, but obviously it depends on the relative proportions of the cross-section. Considering failure in this light, the strengths of the specimens that failed by twisting were predicted within reasonable limits by Equation (6).

TRANSPORTATION DEVELOPMENTS IN THE UNITED STATES

By Fred Lavis,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Milton Harris, Ralph Budd, L. Alfred Jenny, William J. Cunningham, S. R. Truesdell, David A. Molitor, C. A. Hoglund, and Fred Lavis.

Synopsis

A broad review of the problems facing transportation in the United States is offered in this paper, with sharpest emphasis placed upon the problems facing the railroads. Of the five important transportation agencies—railways, highways, waterways, pipe lines, and airways—railways are shown to be the most important.

Special stress is laid on the need for adequate research on a large scale and broad basis into the problems confronting the railroads, both for their proper rehabilitation and necessary progress. The writer considers that the prosperity of the railroads is essential to the prosperity of the country as a whole. The railways are in grave financial difficulties, maintenance is greatly deferred, and progress is not being made. This is due to fundamental defects in governmental regulation rather than loss of traffic due to the general depression. It is believed that there should be better co-ordination of all transport facilities and direct governmental aid or extension of credit should be provided for the railways as it is now being extended to all other forms of transportation.

Importance of the Railways

Twenty-five years ago, when people spoke of transportation in the United States they thought only of railways. At the present time, the railways comprise, as a group, only one of five important transportation agencies—railways, highways, waterways, pipe lines, and airways—all important factors in transportation. Twenty-five years ago the automobile was scarcely out of the crawling stage; the truck, the tractor, and the motor bus were unknown. Aviation was an experiment, pipe lines were not a factor to be reckoned with, and the waterways were little used. Inland waterways had declined as a factor

---

Note.—This paper was presented at the Annual Convention, Salt Lake City, Utah, on July 20, 1938, as part of the Symposium on Transportation, and published in November, 1938, *Proceedings*.

[1] Cons. Engr., New York, N. Y.

in transportation as the railways advanced, and they had not yet come to the stage of heavy development in physical structure through the use of Government funds and Federal capital invested in operation.

In spite of the development of these competing forms, however, the railways are still the dominating factor in the field of transportation in the United States; that is, they are dominating in the sense that they move by far the largest volume of freight over the longest distances and, consequently, they are dominating in their relation to general business and industry. With highways so easily visible, and with the dramatization of air travel, the public tends to forget this position of the railways and the fact that they move considerably more than twice as much freight as all the other agencies combined. Exact data as to this distribution are not available, but the following is a reasonably correct estimate of the distribution, between the different kinds of carriers, of the ton-miles of freight handled in 1936:

Description	Ton-miles, in millions	Percentage of total
Steam railways	341 181	67.5
Waterways	92 651	18.3
Motor carriers (highways)	40 227	8.0
Pipe lines (petroleum)	30 710	6.1
Electric railways	704	0.1
Total	505 473	100.0

This list does not include intra-urban transportation. In referring to this classification Mr. Joseph B. Eastman, Member of the Interstate Commerce Commission and formerly Federal Co-Ordinator of Transport, has demonstrated [2] that the ton-mile data do not show the relative effect of highway competition inasmuch as truckage hauls, on the average, are comparatively short. Comparison on a tonnage basis shows a higher percentage of actual tons hauled by trucks, at considerably higher and more profitable rates.

In general, the average cost (to the shipper) of freight hauled on the railroads is slightly less than 1 cent per ton-mile whereas the cost of haulage by truck [3] is from 5 to 7 cents per ton-mile. It is to be realized, of course, that the truck haul is from door to door, whereas the railway haul is the cost of movement on the rails alone.

Another estimate of the relative importance of the various carrier agencies is given by John S. Worley,[4] M. Am. Soc. C. E., as follows:

Description	Gross revenues for 1932	Percentage of total
Steam railways	$3 168 537 000	83.03
Great Lakes	11 733 099	0.31
Pipe lines (oil)	211 788 647	5.55
Inter-city trucks for hire	164 728 000	4.32
Inland waterways	8 572 965	0.22
Electric railways	70 865 505	1.86
Inter-city buses	171 200 000	4.49
Airways	8 600 000	0.22
Total	$3 816 025 216	100.00

[3] "Motor Truck Freight Transportation," U. S. Dept. of Commerce, 1932.

[4] *Engineering News-Record*, June 11, 1936.

These values afford some interesting comparisons although they are for 1932 and the prior list is for 1936. Comparison of the two tabulations serves at least to indicate the very low ton-mile costs to shippers on the waterways as compared to those on either railways or highways. In making these comparisons, however, it must be borne in mind that total costs of transportation are from door-to-door and although, undoubtedly, costs of movement in barges or vessels on waterways are low, they do not necessarily show total costs from origin to destination; neither do they include costs of building and maintaining the waterway itself.

HIGHWAY CAPACITY

It is not possible in the United States, on the basis of present knowledge or expectations, to substitute highway transport for railways for the movement of freight on a large scale. For example, consider the freight movement on the Pittsburgh Division of the Pennsylvania Railroad, which extends between Pittsburgh and Altoona, Pa., a distance of 113.9 miles. On a representative day in 1938, a total of 162 756 net tons of freight was moved in 108 freight trains, containing 4 089 loaded cars, and manned by approximately 575 employees. To move a similar volume of freight by highway, in 5-ton trucks, would require 32 551 vehicles, each manned by at least one employee. If these vehicles were spaced the legal distance of 500 ft apart required by the Pennsylvania State law, they would cover a total of 3 084 miles of highway, or about the distance from Los Angeles, Calif., to Philadelphia, Pa.; and, moving at the rate of 25 miles per hr, would require 123 hr, or more than 5 days, to pass a given point.

Assuming 6 000 motor vehicles per day (that is, vehicles moving in both directions which is a reasonably dense traffic as the normal capacity of a first-class, two-lane highway), it is evident that this freight alone would require about five or six of such highways to handle it. If only half the total traffic were trucks—the remainder being buses, private automobiles, and other vehicles—it would require ten or twelve such highways through this one section of the country to equal the capacity of the one railroad.

Of course, there are several ways of estimating this highway capacity as, for instance, assuming 10-ton, instead of 5-ton, trucks; the fact, however, that the rail traffic cited is fairly representative of an ordinary day must also be considered, but in both cases provision must be made for peak loads. The railroad could handle twice as much traffic on the same trackage; but to handle twice as much in the same period of 24 hr on the highways would require twice as many highways.

The railways are not only important because they now handle by far the largest proportion of the freight but because there now seems no other way in which this traffic can be handled. Furthermore, the World War demonstrated the absolute necessity of railways in time of war.

PRESENT STATUS OF THE ART OF TRANSPORTATION

Highway Developments.—The very important subject of highways and motor-vehicle development has been ably treated by Charles F. Kettering[6] and L. I. Hewes,[6] Members, Am. Soc. C. E.; but attention may be called to one phase of the subject, namely, the effect of the speed of motor vehicles on highway design. There are those who claim that all present-day highways are obsolete; that they are out of date as soon as they are built because they are not designed for speeds of 100 miles per hr. They claim that the modern automobile (and possibly, the modern truck) can be, or soon will be, driven safely at this speed; that engineers are lacking in foresight and are hopelessly conservative and behind the times if they do not recognize this need in the design of highways. These writers ignore the fact that only a small proportion of drivers of motor vehicles are capable of driving at speeds in excess of 50 or 60 miles per hr under ordinary every-day conditions.[7] Engineers must take the human element into consideration and not be carried away by too much enthusiasm for modern scientific and mechanical triumphs which, in some cases, may be beyond the ability of the public to use.

---

[6] "*Proceedings*, Am. Soc. C. E., June, 1938, p. 1116.

Aviation.—It has been predicted [8] by J. Monroe Johnson, M. Am. Soc. C. E., Assistant Secretary of Commerce, that within a short time 10-hr transcontinental schedules will be established, with great air liners flying in the substratosphere, as well as non-stop sea schedules between New York, London, and Paris; and 40 000 000 persons instead of 400 000 will be using the air regularly for travel. Spencer R. Newman, District Traffic Manager of the United Air Lines, has described [9] the status of aviation in considerable detail.

Realizing that great strides have been made in aviation in recent years, and quite believing that the prediction of Colonel Johnson is not altogether an iridescent dream, the writer doubts that aviation will, for a long time to come, take care of much more than the "cream" of normal increase and the increase in travel which aviation itself creates.

Aviation, highways, and waterways, are handicapped by bad weather conditions to a much greater extent than the railways, and all-year-round, daily, and hourly reliability is still an important factor in the business of transportation.

Waterways.—The subject of navigable inland waterways has been discussed quite fully by R. W. Putnam and S. L. Wonson,[10] Members, Am. Soc. C. E., and C. L. Hale,[11] M. Am. Soc. C. E., who present, quite fully, the arguments for and against these Government subsidized lines of transportation.

The investments of Government capital and the use of Government subsidies under whatever guise they may appear (and in the case of the waterways it is not difficult to recognize them) is a very important consideration in dealing with the transportation problem, but the writer doubts very much if the general public has any idea of the extent of this phase of Government activity, the facts in regard to it, and its effect.

Pipe Lines.—Pipe-line operation is a purely commercial development, and is really an extension of the oil-refining and distributing plants of the oil companies. It is part of the system of production, refining, and distribution of their products. The business—the freight—is supplied by the owners of the transportation agency and is part of their business.

Railways.—The development of light-weight Diesel engine trains has been traced by Ralph Budd,[12] M. Am. Soc. C. E., and C. P. Kahler,[13] Assoc. M. Am. Soc. C. E., has described turbo-electric-driven trains.

In the railroad field, at the present time, there are potentialities for improved service, and for the reduction of operating costs, which would almost revolutionize the railway industry and with it create improved business conditions in all industry. Under the conditions obtaining on the railroads to-day, however, these potentialities can bear full fruit only if the human element, financial considerations, and political thought keep step with them. Prosperity and sound business conditions are indispensable for such advances.

Prospect of Improvement

Need of Research.—Not long ago advances and developments in engineering and mechanics were products of the thought and research or genius of individuals. Such progress to-day, however, is mostly the result of intensive study by large groups and combinations in laboratories. No longer is this progress the result of the work of the lone man in a garret; it is the co-ordinated effort of large groups of well-paid scientists. They work on definite plans, toward definite objectives, in well-equipped laboratories with, on the one hand, huge testing machines and, on the other, the most delicately made and finely adjusted scientific instruments. Such progress means the expenditure of money. It is supported by groups of large businesses that are prosperous and by this means help maintain their prosperity.

Although a certain amount of research is being conducted by the railways, it is scattered, not well co-ordinated, and is not on a scale that the industry warrants. Some of it is scattered among the colleges and thus is useful, but there is need of a large centrally located and well-equipped laboratory where all these efforts can be supervised.

Advances Depend on Human Element as Well as Science.—Steps are being taken and methods are being put into practice to try to solve at least one of the very difficult problems which the railways have had to face, namely, the loss of passenger business. Attempts to encourage passengers to return to the railways do not begin, however, to touch the fundamental difficulties in which the railways of the United States now find themselves involved. Meritorious though these improvements in passenger service may be, and valuable though they may be in indicating what may be accomplished in the entire field of railway transportation, they should not be allowed to obscure the effects of the much more important factors in advances—the human element, the political element, and the underlying financial difficulties of the railroads to-day.

---

[12] *Civil Engineering*, September, 1938, p. 592.

[13] *Loc. cit.*, August, 1938, p. 509.

Recently, the writer experienced the entire gamut of transportation development in one short period of less than two months. He traveled by primitively equipped train, by automobile, and by truck over badly worn dirt roads and no roads, by ox-cart, by mule wagon, motor-boat, horse-back, mule-back, and on foot, over an area about 300 miles in length which required actually five weeks of strenuous endeavor. Then he returned, in the air, over or above the same route, by a regularly scheduled airplane, in 1½ hr. In studying the ways and means of improving the land transport over this route the writer was impressed by the part that had to be played by Man, the human being, by politics, by finance, by commerce, and by economic considerations. All these factors came into play in finding a solution for the problem. The engineering aspects were simple compared to the human, political, and financial aspects.

Advances in transportation, or advances in other fields, mean more than the improvement of existing machines, or the substitution of a new machine for an old one, a Diesel engine or a turbo-generator for the steam locomotive, or the improvement of the steam locomotive itself.

In evaluating the worth of such improvements as increase in speed, stream-lined trains, Diesel engines, electrification, light-weight cars, modernistic design of passenger coaches, and improved freight services, one must have some picture of the railroad situation as a whole and its relation to other transportation developments. If the railroads are "sick," as they are if they are all going into bankruptcy, and they seem to be tending that way, it is of little moment whether or not trains are stream-lined, or whether the decorations in the lounge cars are modernistic, futuristic, or sur-realistic.

Surplus of Facilities.—The outstanding feature of the transportation situation in the United States is the surplus capacity of the combined transportation facilities in relation to the business there is to be done. During the World War, the railways, then virtually the only transportation agency in the country, broke down under the volume of business offered. In the years immediately following, large investments of earnings and capital were made to improve and increase their facilities so that, with the boom period of 1927–1929, they handled the very large volume of business then offered without difficulty.

Government Capital in Highways, Waterways, and Airways

In the meantime, highways were being extended, rebuilt, and repaved, waterways were being improved for navigation, and air lines were beginning to be a factor. The first two were built entirely with Government capital, and the airways were developed under substantial Government subsidies. (Government will be understood to mean not only the Federal Government, but also that of the States, counties, and municipalities.) It is fair to state that, although the highways were, and are being, built with capital furnished by the Government, a considerable part of it came from direct taxes on the vehicles and their operators, and that the subsidies to aviation have been warranted both for mail service and on the score of developing the national defense. It has been announced, however, that the State of Pennsylvania is to provide the sum of $58 000 000 to build a new highway from Pittsburgh to Harrisburg, Pa. Of this, $32 000 000 is to be a public loan and $26 000 000 a grant. The loan is expected to be repaid from tolls.

The subsidies to the waterways—that is, the Government investments in waterway improvements—have been justified or excused, in part, on the plea of flood control, or power development, but in the Mississippi Valley they have been made frankly and almost wholly for the improvement of navigation.

The point to be made, is, that the capital for this expansion of highways, waterways, and part of that for airways, was furnished by the Government.

INCREASES OF TRANSPORTATION FACILITIES

In his report of March, 1934,[2] as Federal Co-Ordinator of Transport, Mr. Joseph B. Eastman called attention to the fact that in 1920, when the railways had a virtual monopoly of transport, their total investment was approximately 19 billion dollars. Between 1920 and 1932 investments in additional transportation facilities amounted to an additional 20 billion dollars, divided as follows:

Transportation agency	Millions of dollars
Railways, additional	6 300
Pipe lines	424
Streets and highways	12 500
Waterways (U. S. Government)	604
Total	19 828

There were some decreases due to abandonment of electric railways, but the investment in transportation facilities was doubled in that 12-yr period, 1920 to 1932. One-third of it was private capital invested in the railways, and almost two-thirds was Government capital invested in highways.

One of the fundamental aspects of the present-day transportation problem, therefore, is a very greatly increased capacity, a surplus capacity over and above the needs of the country, and the continued and continuing investment of Government capital in additional transportation facilities. It is probable that this surplus capacity would not be so evident or nearly as large if the country had gone ahead at a normal rate of growth during the ten years, 1928–1938, but with depression succeeding depression this increase in capacity becomes one of the major factors in the present situation.

With the almost inevitable further continuance of growth of highways on a large scale, this surplus capacity is not likely to be reduced by population increase or growth of business. This problem, therefore, is likely to continue for some time, aggravated by certain factors that reduce freight traffic permanently.

Passenger Traffic.—Whether or not the passenger traffic can be restored to railroads, or further loss prevented, is difficult to judge. Speaking before the Western Railway Club, at Chicago, Ill., on January 20, 1936, W. W. Colpitts, M. Am. Soc. C. E., expressed great hopes that it might be, by reason of better and faster service. The writer believes that much of the passenger business is lost permanently to the private automobile; but there is a substantial volume that can probably be retained and possibly increased by improvements in service. It is a question, however, if some of this business is not being carried at a loss.

Among some of the adjustments that will be brought about by re-organization and also by voluntary action on the part of the railroads (with the permission of the Government) will be the abandonment of services that do not pay. On July 9, 1938, Federal Judge Carroll C. Hincks over-ruled the Massachusetts Department of Public Utilities and ordered the elimination of eighty-eight passenger stations on the Old Colony Railroad. In his decision he stated that re-organization is impossible, legally and economically, for a railroad that cannot earn its operating expenses. To continue the passenger service of the Old Colony Railroad on the old basis would have jeopardized its capacity to maintain the indispensable freight service in that territory.

Although the changes in service will be inconvenient to some, they were judged to be in the public interest, permitting more satisfactory service for others, and it was reasonable to assume that transportation by highway would be available for those who found themselves without service by rail. Furthermore, according to the decision, the public interest would be served better by a policy protecting indispensable freight and passenger service than by a policy which daily was bringing nearer the destruction of the entire enterprise.

Freight Traffic.—Certain factors that adversely affect the freight business of railways, however, will undoubtedly be permanent. The transportation of coal has not only failed to increase with the increase of population but has actually diminished due to the use of fuel oil and electricity. Both oil and gasoline are now transported by pipe lines and these commodities have the double effect of replacing coal and taking the business from the railways. The decrease in foreign trade, which is not likely to be revived, has decreased the traffic in imports and exports. Much l.c.l. (less car-load lots) freight, especially short-haul freight, is being carried by trucks on the highways, some of these, however, being operated by the railways themselves. The transportation of raw materials has been diminished due to the moving of factories to new locations near sources of supply of the materials they use. Many economies have been introduced by manufacturers to reduce transportation as well as other costs of production.

There is no new territory to develop, the rate of increase in population has decreased, and there is no new immigration. The net remainder, therefore, is a greatly increased transportation capacity and with it certain special factors that reduce the volume of freight to be transported. On "the other side of the ledger" is a certain amount of new business from the automobile industry and the fairly large volume of business that comes to the railways in hauling supplies for the construction of highways and other public works financed by the Government. Some of these benefits will continue unless the nation reaches its limit of borrowing or devaluation, or decides to balance its budget.

One particular phase of freight movement on the railways, which has been developed within recent years, is the need of speed in the movement of certain kinds of goods.[14] Until a comparatively short time ago, large inventories were the rule and orders were placed for quantities to cover seasonal rather than daily or weekly requirements. Then came the present era of small inventories, quick turnover, and so-called "hand-to-mouth" buying.

---

[14] *Railway Age*, December 23, 1933, p. 872.

To-day, orders are placed by telephone and deliveries from distances as remote as 500 miles may be expected the next day. The result is the development of freight trains traveling at night at speeds of 40 to 50 miles per hr which presents a very different situation from that which obtained 30 to 35 yr ago when grades of 0.2%, 0.3%, and 0.4% were built for heavy trains traveling at 14 to 15 miles per hr, and when shipments were often a week or more on the road.

IS THERE A RAILROAD PROBLEM?

The extent of the decline in the business of the railroads is indicated by the data in Table 1. In 1936, Mr. Worley [4] ridiculed the idea that there was then any national transportation problem. He claimed that the railroads were no worse off than other industries and that all were suffering alike from the economic debacle of 1929. Nevertheless, about 75 000 miles of railroads are in the hands of Receivers or Trustees in Bankruptcy to-day (July, 1938), and others seem to be seriously threatened. On July 1, 1938, the Superintendent of Banks of the State of New York announced that more than $3 000 000 000 face value (principal sum) of railroad bonds had been stricken from the list of legal investments for the savings banks of the State. This evidence lends the general appearance of a crisis or, at least, of a gravely serious situation.

TABLE 1.—DECLINE IN RAILROAD BUSINESS, CLASS 1 RAILROADS

Item No.	Description	1920	1926	1929	1932	1934	1935
1	Freight originated, in millions of tons	....	....	115.3	....	....	76.3
2	Freight carried, in billions of ton-miles	....	....	447.3	....	....	282.0
3	Gross revenues, in billions of dollars	....	6.3	....	....	....	3.4

5	Passenger traffic, in billions of passenger miles*	47.0	....	....	....	18.0	....

* *Railway Age*, February 1, 1936.

It must be borne in mind that the railways cannot be compared with ordinary industry, such as a steel mill, a copper mine, a textile plant, or other similar industries, any of which can be shut down in times of low demand. The railroad is compelled to run trains, its need for maintenance goes on more or less regardless of traffic; the service to be rendered, and the rates to be charged are subject to regulation by the Government; and the wages it must pay its employees are (or may be) determined by another governmental agency.

In times of stress the railroads must stop maintenance, stop buying, stop improvements, stop advancing, and this cessation has a very serious reaction on the country at large. During the seven years, 1931 to 1938, the railways are reported[15] to have spent only 49% as much money annually for maintenance as was spent annually in the five years, 1925 to 1929, inclusive. It is estimated that the deferred maintenance at the end of 1937 was approximately a billion dollars.

---

[15] *Railway Age*, January 1, 1938, p. 22.

This is partly a matter of judgment but the detailed data cited make it seem reasonable. Keeping maintenance up to date, however, is not advancing, but there can be no advancement at all with any substantial amount of deferred maintenance. Advances cannot be expected in an industry which is in the condition in which the railroads find themselves to-day. If it is true that nothing stands still, then the railroads are going backward, and if they are (and the writer believes they are) it is a serious situation.

Perhaps it is true that the difficulties in which the railroads find themselves are not symptoms exclusively of the railroads but are symptoms of a badly adjusted national economy, the attack on the profit motive, and the drift toward socialistic government ownership of everything. The railroads, however, seem to be bearing the brunt of the attack and, therefore, the problem now is a railroad problem.

Needs of the Railroads

Need of Lower Costs of Operation.—So far as the railways are concerned, economy in the cost of operation means producing ton-miles and passenger miles at the lowest cost consistent with the full movement of traffic, and with the value of the facilities used and service rendered. The last is fundamental. This is particularly so because the service of the future must be much better than that of the past, and must continue to improve.

Labor.—One of the most important factors in this phase of the problem is the cost of labor. According to Thomas F. Woodlock [16] wages to all workers on the railroads now constitute more than 60% of all operating costs and, therefore, they are a most important factor in the situation. Service depends very largely on the human element.

Every one is entirely in favor of adequate compensation for labor—that is, compensation for all those employed from executives to track walkers. However, when special groups of employees banded together for mutual protection (as they have a perfect right to be), use their combined voting strength or group pressure to obtain unfair advantages for this group at the expense of others, or obtain privileges not granted to labor generally, it is not conducive to sound business for the country or the industry.

The very powerful unions of the railway workers have not always worked in the interest of the railroad industry retarding many otherwise possible advancements and, incidentally, injuring their own cause.

There seems to be no good reason why railway employees should be specially singled out and favored over other classes of labor by general legislation as, for instance, in the special Social Security and Pension Acts, applying only to railway employees, passed at the last session of the 75th Congress when this same Congress was too busy to heed the President's plea for substantial relief to the railroads.

There are many angles to the labor question and having been a laborer all his life the writer is entirely in favor of having labor get all the pay the traffic will bear, with reasonable hours of labor and security for old age, but if any or all of these demands are applied unreasonably simply to provide jobs and not to promote efficiency, adjustments will inevitably have to be made, or the jobs will disappear.

---

[16] *New York Sun*, January 8, 1936.

That railroad labor has not lagged behind in increases of wages is indicated by the following data cited by Mr. Robert V. Fletcher[17]:

> "The average hourly compensation of railroad employees has increased from 28.3¢ in 1916 to 68.6¢ in 1935, an increase of 142.4%, while the cost of living has increased only 26.8 per cent. The average annual pay increased in this same period from $892 to $1 653, nearly double; but note this, the average number of persons employed dropped from 1 647 097 to 994 371, not much more than half."

Part of this decrease in employment has been due to economies in operation by increasing the number of cars and tons per train, longer runs, elimination of certain terminal and intermediate yards, etc., but these operating economies by the railroads have been more than offset by decreases in the rate level, both freight and passenger, and the general decline in business. The working of the seniority rule has tended to keep an unduly large number of older employees in service and to stifle the ambitions of the younger men, a situation which tends to devitalize the industry.

It is not only that wages to railway employees increased considerably during the twenty years, 1916 to 1935, but these increases have continued through the depression.

At the end of 1937 the bill for wages on the railways was increased by more than $100 000 000 per yr at a time when operating revenues were seriously declining.[18] The result was further curtailment of buying by the railways, an accentuation of the decline in general business activity, and, of course, further decline in business (that is, freight, handled by the railroads) and, a further laying off of large numbers of men. The National Mediation Board which obtained "peace" with the labor unions by granting this increase, did not improve either the general business of the country, the position of the railroads, or, in reality, the economic status of the railroad employees. It is not a healthy condition to have earnings of trainmen increased 16% while average net earnings of the railroads decreased 70 per cent.[19]

The labor question on railroads is a tremendous problem which cannot be ignored. If the railroads of this country are to maintain and improve their position (and there can be no general prosperity without prosperous railroads), labor must do its part in producing ton-miles at the lowest possible cost, and must provide improved service. If this means sacrifices either in number of employees due to more efficient machines, or lower rates of pay, these sacrifices will have to be made; but intelligent co-operation on the part of labor can help produce lower costs without such sacrifices through greater efficiency in operation which, in turn, means better service at lower cost.

The automobile industry is probably the most highly mechanized of any in the country, the value of the product of each man's labor is higher than that of any other industry, and the rates of wages are at the top. This has not been achieved by "made" work but by securing the maximum production from the proper combination of men and machines. Railways will have to achieve something similar to regain and hold prosperity.

---

[17] Address to the Academy of Political Science, November 12, 1936, p. 62.

[18] *Railway Age*, January 8, 1938 (quoting from *Washington, D. C. Post*).

[19] Associated Press Dispatch, in New York paper, June 30, 1938.

It must be evident from the foregoing that reduced revenues and increased costs of operation (labor being an important influence in the latter) are two outstanding factors affecting the railroad situation in the United States to-day.

Railroad Capitalization.—There is little use in discussing the present financial structures of the railroads. It has been shown time and time again that the railroads are not over-capitalized. Considerable of the existing capital will probably be lost in the various re-organizations and bankruptcies through which so many of the lines are now passing. The diminishing rate of return on the capital invested in the railroads is shown in Table 2.[20]

TABLE 2.—RAILROAD CAPITALIZATION

Year (1)	Net operating income, in dollars (2)	Annual rate of return (percentage) (3)	Year (1)	Net operating income, in dollars (2)	Annual rate of return (percentage) (3)
1928	373 871 000	5.03	1933	132 595 000	1.93
1929	311 735 000	4.04	1934	118 946 000	1.79
1930	223 692 000	3.10	1935	175 696 000	2.57
1931	121 863 000	1.74	1936	232 782 000	3.53
1932	130 875 000	1.80	1937	119 161 000	1.66

It is very evident that the railways need considerably more capital in order to bring their maintenance up to date, to make advances, and to take advantage of such improvements in the art as are now available in order to produce ton-miles and passenger miles at the lowest possible costs consistent with the improved service which is now being, and will be more and more, demanded in the future.

Present Needs of the Railways.—High-speed, well-equipped, smooth-running, air-conditioned, and probably lighter-weight passenger trains, are needed. Perhaps it is not going too far to state that it would pay to replace most of the present passenger equipment before 1948. Certainly that is true of main-line equipment, except for the comparatively few trains recently put in service. Genuine research is needed, and a mass of facts as to complete costs per unit of transportation of some of the newer forms of equipment and motive power.

The state of the art of building lighter equipment has progressed to the point of planning for an even greater program of replacement of freight equipment than that indicated for passenger equipment. There are possibilities in mechanical refrigeration and other improvements in the mechanical features of freight cars, trucks designed for high speeds, improved draft rigging, air-brakes, etc.; and yet, it is doubtful whether the industry is even making the beginning of a showing into research as to the possibilities of these improvements.

To carry the new equipment and to operate trains at the high speeds to be demanded in the future, considerable attention needs to be paid to the track and signals. No one seems to have been able to improve on the general form of track structure from that of the earliest days; but heavier rails are needed, as are probably welded rails, improved fastenings, still further lengthening of the useful life of ties, more ballast, better drainage, and, of course, elimination of many grade crossings and some revisions of alignment.

---

[20] *Railroad Age*, February 12, 1938.

The art of signaling is well advanced and undoubtedly the general installation of some of the newer forms of automatic signals will not only promote safety, permitting increases of speed, but by reason of their efficiency, pay for their original cost.

Railroads have only begun to explore the possibilities of power production. The few examples of electrification, of course, mark important advances, but, in the present state of the art, installations of this kind must be confined to areas of very dense traffic, not only because of cost but from their very nature. The overhead wire system of power transmission seems to be tremendously costly and complicated and perhaps one of the advances in store for railroads is a better means of transmission from the power station to the electric locomotive.

Railroads are experimenting with Diesel engines but these have not yet progressed much beyond the experimental stage for general railroad traction inasmuch as all is not known about their total expense in producing and using power.

The steam locomotive is continually advancing in efficiency and steam as a prime mover is yet the "king" as far as most railroads are concerned. However, there are many more old steam locomotives in service than is desirable, and these should be replaced with modern power.

All these and a myriad other factors can, and should, be developed and put into practice to produce a really efficient railroad transportation machine. Brains, knowledge, and the engineering and scientific ability are available, and nothing is needed but money.

THE MONEY QUESTION

Needed Highway Expenditures.—At the meeting of the Greater New York Safety Council, in New York, N. Y., in 1937, Frank T. Sheets, M. Am. Soc. C. E., read a paper on "The Highway of Tomorrow." He discussed, ably and in great detail, not only the probable future traffic of the highways and their needs but also the economic factors—the costs of delays and the congestion due to lack of sufficient highways of the highest types. According to Mr. Sheets:

> "The blindest can see that tomorrow's highway system must include many classes of facilities. Neglect of one class will cripple the efficiency of all others. The metropolitan citizen must grasp the viewpoint and needs of the small town resident and the viewpoint of the farmer. The latter must see metropolitan highway needs. All must grasp the whole highway picture. Narrowness of vision, selfishness of concept, suspicion, intolerance and misunderstanding are the most formidable barriers to the realization of adequate highway transportation. Planning, engineering and financing are relatively small problems when compared with the public educational work and legislative action which must precede accomplishment."

These sentiments are important and are equally applicable to all transportation problems. They should by no means be confined to those of the highways; and, they certainly apply to railways. After this summing up of the situation the speaker then proceeded to forecast a reasonable estimate of the additional investment which he considered "was required to realize the highway system of tomorrow," and this he fixed at the very modest sum of $57 000 000 000.

Government Funds and Credit.—All this money, of course, is to be provided by Government credit and, again, without discussing the question as to whether the motor vehicle operator or owner will eventually pay his share of it consider what would happen to the railways of the United States if one-tenth this sum (that is, the mere bagatelle of, say, $6 000 000 000) were placed at the disposal of the railways for rehabilitation and progress. Like the owner of the motor vehicle the railroad should then be allowed a fairly wide freedom of operation within the limits of fair dealing with shippers, passengers, and employees.

The Government is extending its credit to the highways and, therefore, incidentally to highway motor transportation and to airways. Assume that this investment will be repaid by taxes or other contributions of the users of these facilities. The fact remains that the Government is financing this progress and looks to the development of business, and to the future users of the facilities, for a return on its investment. In these enterprises the Government takes the place of the bondholders and the stockholders of the railways.

There can be no question but that the Government investment in waterways is a special gift by the entire nation to a small section of the population that can take advantage of these facilities. There is little return on the investment, and there is a further annual expenditure for maintenance. Only recently it was proposed also to invest further millions of public funds in building a system of waterways, permitting the passage of ocean-going vessels from the Great Lakes to the sea, an addition to transportation capacity not needed at all and, from the point of view of many, entirely unsound economically.

Political Aspects.—The Government is a most important factor in this railway situation. If the most important section of the national transportation system is to advance, the Government must do its share. It has undertaken for many years now, to regulate and formulate the policies of the railways in minute detail. It fixes the maximum revenues, it allows or disallows capital issues, it regulates rates and hours of labor, etc. In view of the financial aid it gives to other forms of transportation (which it does not regulate so closely) it should extend some financial aid to the railroads, perhaps only to the extent of the $6 000 000 000, one-tenth of that which highway experts say must be spent on the highways to meet the needs of the motor vehicles. Even quite a little less than this would be very useful.

As early as October, 1932, the President of the United States, speaking at Salt Lake City, Utah, said:

"There is no reason to disguise the fact that the railways as a whole are in serious difficulty, and when so large a part of the American people have a direct cash stake in the situation—our job is neither to howl about a calamity nor to gloss over the trouble but patiently and carefully to get to the bottom of the situation—and try to plan for the removal of the basic causes of that trouble."

Many things have been accomplished by the Government since the President made this statement but the basic causes of the "serious difficulty" of the railways have not been removed.

Between 1932 and 1938 the railroad situation, except for a slight flurry in the early part of 1937, got continuously worse and on April 11, 1938, the President in a special message to Congress[21] declared: "Immediate legislation is, I believe, necessary at this session in order to prevent serious financial and operating difficulties between now and the convening of the next Congress."

However, in a recent "Fireside Chat" to the people over the radio, the President complained to his audience that: "The Congress also failed to meet my suggestion that it take the far-reaching steps necessary to put the railroads of the country back on their feet."

In spite of the request of the President for immediate relief and in spite of the appropriation by this same Congress of between $4 000 000 000 and $5 000 000 000 for various public works, which undoubtedly will include further construction of highways, waterways, and airways, nothing was done about the relief to the railroads which the President said was so greatly needed. However, in June, 1938, this same Congress did find time to pass special legislation for the railway employees.

SUGGESTED REMEDIES

Consolidation and Co-Ordination.—The questions of consolidation, co-ordination, and competition are always foremost in any discussion of the railroad situation. Personally, the writer is opposed to consolidation when carried to the extent of building up such large organizations that they lose the sense of personal management. There are undoubtedly cases where further consolidation may be desirable, but these should be studied as individual cases rather than on the basis of some arbitrary plan for the grouping of all the railroads of the country, or of some section of the country.

Co-ordination is being developed between the railways and the highways, waterways, and airways. The experience of the Federal Co-Ordinator of Transport, however, has shown that this is no one-man job; probably it must be developed along the lines of natural growth—in other words, by the American method rather than that of governmental paternalism.

Competition.—Competition has two aspects. In one sense competition is waste, inasmuch as it involves the use of duplicated facilities, but, in the case of the railroads, it is not as injurious or wasteful as it may seem on the surface. The second aspect, which compensates for any disadvantages of the first, is that competition is a healthy state for an industry such as railroad transportation, which depends so much on the human element which, in turn, competition tends to keep alert. There is certainly competition in commercial highway transportation and in commercial aviation. It would be wise to continue reasonable competition in the railway field.

---

[21] H. R. Doc. No. 583, 75th Cong., 3d Session, April 11, 1938.

In a review of the railway situation presented to the Alumni Association of the Harvard Business School on June 17, 1938, Mr. Eastman referred to the various "schools of thought" in suggested remedies for the present situation of the railways which he said were sick, financially speaking, and are the subject of general and grave concern.

He referred to the school of thought that believes that the solution of the problem is to be found in putting the capitalization of the companies "through the wringer"; another school believes in raising rates and fares; and another believes that the entire trouble is that of wages and working conditions.

He emphasizes the fallacies of the first two and says of the third that although drastic changes in the wage scale are not feasible, he does believe that adjustments are necessary. He finally expresses the belief that, in view of the position it has taken and built up in the past, the Government must be an important factor in the necessary rehabilitation and building up of the railways.

Mr. Eastman states that, inasmuch as the Supreme Court has ruled that transportation is a "function of the State," essential to the welfare and well-being of the entire community, the Government must play a more active part in the field of planning, promotion, and prevention.

THE SOLUTION

Now, what is the answer to all the foregoing questions? They all revolve about one question—advances in transportation. The railways are clearly the largest factor, and it is evident that they must be maintained in that position if the country is to continue to prosper and if general industry is to be served. Nevertheless, the railroad industry, on the whole, is going backward instead of advancing and this is not due, except in degree, to the present depression. It will not be really cured by such advance in prosperity as can now be visualized.

The labor situation needs adjustment. If the railways must compete with other industries for business they should be allowed to compete and "sink or swim" by their own efforts as other businesses must, and this need not involve indiscriminate "throat cutting" on rates.

The writer has avoided the mention of taxes because it is too big a subject for the scope of the paper; but taxes are growing ever larger. It seems as if the tax structure might well be adjusted; but there are many opinions about that and, in any event, it will add little to the present thesis to do more than mention it as a factor in the situation.

Government to Furnish Capital and Credit to Railways.—In the matter of capital needs and credit, the railways should be placed on an equality with highways, airways, and waterways, and they should have the full advantage of Government credit and the supply of Government funds for their necessary rehabilitation and progress. If this is done the Government should be in the same position as to railways properties that it is to the highways; that is, a stockholder looking for a return on his investment to the earnings of the property, after existing funded indebtedness has been taken care of.

Investments that are not legal for savings banks are usually not legal for insurance companies and insurance companies are large holders of railway securities. This, then, is not a question of a few powerful and affluent bankers, or wealthy families, but of almost every holder of a savings account or an insurance policy, and that means nearly all the ordinary, every-day, plain careful citizens of the country.

The loaning of Government credit and capital to these people is at least as much justified as is the loaning of Government money to the manufacturers of automobiles, gasoline, and oil, through the construction of highways on which the automobiles may run and the gasoline and oil may be used.

There seems to be ample precedent for the extension of Government credit and the making of Government loans to the railways, and if the railroads are to avoid the Government ownership and operation to which the President says he is opposed, there is little else that can be done.

There seems to be no valid argument against maintaining the present financial structures intact and subject to the orderly processes of present re-organization proceedings. Railroads have been "shaken down," their weaknesses have been exposed, some non-useful and non-profitable services are being abandoned. The President of the United States has spoken very strongly against Government ownership and operation. Viewing the transportation system of the United States as a whole, therefore, it seems reasonable that, in the matter of credit and capital, the Government should put the railways on a par with the highways, waterways, and airways, and then let them run their own business with a minimum of regulation and interference.

DISCUSSION

Milton Harris,[22] Assoc. M. Am. Soc. C. E. (by letter).—The rise and fall of the American railroad has been treated very thoroughly by Mr. Lavis. After justifying the railroad as the major national transportation facility for long-haul freight and showing the relationship of highway transport to that phase of the problem he lightly touches on aviation, waterways, and pipe lines, as also belonging in the transportation picture.

Improvement in transportation facilities, he notes, has been largely financed by Government aid, except that railroads have not been a beneficiary (of late), but have been beset by governmental regulations as to taxes, rates, and wages. The solution, according to Mr. Lavis, is Federal aid to put the railroads on a par with Government-financed highways, waterways, and airways.

In drawing the deplorable picture of the condition of the railroads of the United States, Mr. Lavis has omitted one vital figure that stalks the background from the beginning of railroad history. To-day, this figure stands out as the foremost agent responsible for "sick" railroads. That figure is "management." This word may be subdivided into financial and operations management; the first is under indictment, and the latter is responsible for the finest system of railroads in the world.

Management that bred the expression "the public be damned" soon led that self-same public to devise regulations to protect their own interests from the depredations of voracious financiers who were not aware that they were in the transportation business. Therein lies the main difference between highway and rail transportation. The highways are not listed on the stock exchange. True, they are in many cases under the control of political pressure groups, but those groups, by their own greedy tactics, are soon ousted, and it is a fair sign of progress that highway engineers are now becoming aware of their heritage in that they are becoming "traffic-minded"—that highways are not merely pavements, structures, and grading quantities, but are vital elements of the transportation problem and should be so designed and operated with that in mind.

About 20 or 25 yr ago railroad managements were presented with many, many miles of feeder road-bed. It was laid in their laps practically free of cost and all they were asked to do was to provide the rolling stock. Because these short-sighted gentlemen could see no ballast, ties, or rail winding into the hinterland, they lay back and allowed a younger, keener breed of executives to populate the highways with trucks and buses that stole the short-haul business. Too late did railroad management "let out a howl to high heaven" that they were robbed.

Lack of money is not entirely the pressing problem of the moment for the railroads. At one time in their history, it was the very least of their troubles; but unredeemed bond issues, structures, plant, and equipment that have paid themselves out many times over, but still appear on the books as capital investment (combined with resulting inflexible rate structures forced on the companies as the result of their own shortsighted policies) have now tied the railroads into a "balled up mess of red tape." Money will not cut the way out except in the hands of modern executives who realize the place of the railroad in the modern transportation scheme and can so co-ordinate that element to the whole that the entire structure is basically in tune with modern needs and economics.

---

[22] Associate Highway Engr., State Div. of Highways, Sacramento, Calif.

"Railroaders" to-day are antiquated. They "railroad" like their grandfathers did. New blood is needed—new thoughts and the application of the newer sciences. How many college graduates do the railroads absorb each year? What possible incentive under the present regime is held out for such men that other major industries seek so avidly? Where are the railroad research laboratories? What contributions have the railroads recently made to civilization where the crying need of the hour is more economical distribution of the products of labor?

These are the questions to be answered by railroad management. With a transfusion of modern executive blood into its system, and a lightening of governmental regulation, the railroad problem will fit itself quietly into the complete transportation picture and its financial worries will not affect civic life to the extent that they do at present. That the railroad has a definite place in the distributive system, no one can deny, but until railroad executives realize that they are in the transportation business instead of in the railroad business, Federal monetary aid to help them in their dilemma will merely be "pouring sand down a rat hole." Reference to Table 3 will clarify this viewpoint.

TABLE 3.—STATEMENT NO. 53 OF THE FIFTEENTH ANNUAL REPORT OF THE STATISTICS OF RAILWAYS IN THE UNITED STATES FOR 1936 BUREAU OF STATISTICS, IN DOLLARS

Year ended December 31 (1)	Investment in road and equipment—book value (Classes I, II, III, lessor, and proprietary companies) (2)	Common stock outstanding (3)	Preferred stock outstanding (4)	Funded debt outstanding (5)	Net capitalization equals total capital less sum of railroad stocks and bonds owned by railroads (6)
1923	21 372 858 000	7 398 000 000	1 852 000 000	13 589 000 000	17 810 000 000
1924	22 182 267 000	7 539 000 000	1 935 000 000	14 162 000 000	18 202 000 000
1925	23 217 209 000	7 602 000 000	1 937 000 000	14 105 000 000	18 191 000 000
1926	23 880 740 000	7 560 000 000	1 925 000 000	14 192 000 000	18 234 000 000
1927	24 453 871 000	7 683 000 000	1 980 000 000	13 951 000 000	18 137 000 000
1928	24 875 984 000	7 809 000 000	2 034 000 000	13 904 000 000	18 511 000 000
1929	25 465 036 000	7 853 000 000	2 065 000 000	14 065 000 000	18 680 000 000
1930	26 051 000 000	8 009 000 000	2 074 000 000	14 248 000 000	19 066 000 000
1931	26 094 899 000	8 031 000 000	2 049 000 000	14 264 000 000	18 941 000 000
1932	26 086 991 000	8 067 000 000	2 047 000 000	14 723 000 000	18 894 000 000
1933	25 901 962 000	8 057 000 000	2 042 000 000	14 624 000 000	18 831 000 000
1934	25 681 608 000	7 994 000 000	2 044 000 000	14 532 000 000	18 653 000 000
1935	25 500 465 000	7 987 000 000	2 036 000 000	14 224 000 000	18 342 000 000
1936	25 432 388 000	7 993 000 000	2 036 000 000	13 974 000 000	18 336 000 000

The sum of Columns (3), (4), and (5) (Table 3) equals the total railroad capital outstanding. Careful year-by-year study of the relationship of the elements of capitalization against book value should indicate the mortgage that railroad management has allowed to accrue against their plant without change in their operating methods. The heritage of past financial evils rides the railroads of to-day.

The railroads pioneered the opening of vast domains of natural resources of virgin country which were soon settled and producing traffic which increased with the years. Then came stabilization of population and industry, followed by the seeking of transportation at a lower price engendered by competition. Highway transport filled this need to a certain extent and decentralization of industry followed to decrease further the rail revenues. As a result there may be a surplus of rail facilities, as Mr. Lavis states, but is that a reason why the consumer or taxpayer should be forced to keep these dying tentacles alive? Would it not be more economical to abandon this surplus, write off the investment and replace it with a cheaper form of transportation plant? Possibly this would lead to a profitable organization, selling transportation at the lowest possible value by using the railroads as a back-bone and the more profitable self-sustaining highways as feeders, aided by pipe lines, airways, and water transport, all co-ordinated and consolidated into a national transportation system.

RALPH BUDD,[23] M. AM. SOC. C. E. (by letter).—The pity is that the information in Mr. Lavis' paper cannot be more widely disseminated and brought home to the general public. Lack of general understanding of the facts, so ably marshalled by him, is one of the primary factors in the so-called railroad problem.

Many thoughtful persons believe that substantial portions of the investments in railways already have been confiscated through low rates and high wages. Almost one-third of the railroad mileage is being operated under trusteeship, nearly one-half did not earn operating expenses and taxes in 1938, about nine-tenths failed to earn taxes, operating expenses, and fixed charges, and only about one-tenth earned anything for improvements or dividends. Education of the public must come from the disinterested studies of transportation experts and not from the clamor of minority pressure groups which have selfish interests.

Mr. Lavis' suggestion that there should be intensive and centralized research will meet with general approval, but more research is now (1939) being conducted than is generally recognized. The Association of American Railroads has done some work, although the extent of its research has been disappointing. Manufacturers of steam and Diesel locomotives, manufacturers of cars, machinery, and supplies, and the individual railroads have contributed to far-reaching improvements made in recent years.

With great deference to Mr. Lavis, the writer is not quite content with his statement that Diesel engines have not yet progressed much beyond the experimental stage for general railroad traction. The Diesels have demonstrated their efficiency and economy in switching service and in passenger train service, expecially on long-distance high-speed schedules. Coincidentally, the newer steam locomotives are greatly improved in design and capacity. Recently some very remarkable results have been obtained by the use of motion pictures in the study of "pound" on track by locomotive driving wheels at high speeds—either actual or slippage speeds. Space forbids enumeration of the many improvements that have been made possible in the last few years by intensive study and research. The daily operation of about 240 000 miles of railroad provides a laboratory in which a vast total of improved methods and devices are being developed all the time. Much of this development is not spectacular or widely publicized, but it is going on day in and day out as the result of the thought and ingenuity which hundreds of railway engineers are devoting to their work.

---

[23] Pres., C. B. & Q. R. R., Chicago, Ill.

As Mr. Lavis states, there is no lack of brains, knowledge, or engineering and scientific ability; what is needed is money. It would be a splendid thing if the railroads could afford to establish a nation-wide railway laboratory, in charge of a staff of skilled engineers. However, there are several financial aspects of that problem. It is not alone the initial cost of establishing such a research laboratory, or the expense of maintaining it, which makes such an investment difficult under the present financial condition of the railroads; the utilization of improvements frequently is disappointing from the standpoint of direct financial return on the investment. For one thing, there are many archaic rules respecting pay and working conditions which are so little adaptable to improved devices that no actual saving can be accomplished thereby. The development of new devices and of light-weight metal alloys of great strength has opened new vistas of building, and operating, light-weight locomotives and cars, which would reduce the ratio of dead weight to total train weight, reduce wear and tear on roadway and rolling stock, and permit faster and safer operation. However, existing equipment which is in serviceable condition cannot be scrapped immediately and replacements can be made only gradually. In the public interest it is desirable to make such replacements largely through depreciation accounts rather than by increasing capital accounts. To do this within a reasonable time requires a higher standard of earnings than has been permitted to the railroads in the past. Frequently there are opportunities for the railroads to make expenditures to take advantage of new ideas, with prospect of large return upon the investment; but as investments in railroads already are so large, and the return so meager, conservative management cannot consistently take any unnecessary risk with the capital available. If private enterprise is to provide necessary funds with which to take advantage of improvements and developments in railroading, there must be greater prospect than in the past that those investing the money will have some chance to share in the benefit of the improvements. It is not enough that the shippers and employees shall be benefited.

Some part of earnings must be paid for the use of money which makes earnings possible. Equipment trust certificates, at relatively low rates of interest, are well regarded by investors because they carry reasonable assurance of security of principal and interest.

Mr. Lavis suggests that the Government should provide funds for the rehabilitation of the railroads, either by loans (see heading, "The Solution: Government to Furnish Capital and Credit to Railways") or by gifts (heading, "The Money Question: Government Funds and Credit"). For a number of years the railroads have been borrowing money from the Government, chiefly through the Reconstruction Finance Corporation, and such loans, designed to tide over railroads that could not obtain money elsewhere, have been of great assistance; but such loans are merely temporary assistance—not a cure. In so far as the aggregate of railroad debt is increased in that manner, the day of reckoning is simply postponed; and, ordinarily, increasing the debt load reduces the credit.

Mr. Lavis makes a plausible statement of reasons why the Government well might grant the railroads a subsidy of several billions of dollars, in view of the much greater financial aid it is giving to other agencies of transportation. The writer does not think that Government subsidy should be considered as anything but a last resort. The capitalization of the railroads as a whole is below the valuations made by the Interstate Commerce Commission and, on the whole, the fixed indebtedness is not excessive. The railroad problem would not be solved by reducing fixed charges through writing off losses of investors, nor by Government loans without interest, nor by subsidies, unless it is to be solved through resort to Government ownership. If investors are to put new money into the railroad industry, what is needed is an increase in net railway operating income and elimination of unnecessary expenditures, not devices for expediting the so-called "wringing process."

To increase net railway operating income, the rate-making rule of the Transportation Act of 1920, which was practically eliminated by the Act of 1933, should be restored. In substance, the 1920 rate-making rule directed the Interstate Commerce Commission, in regulating rates, to permit the carriers as a whole, or in groups selected by the Commission, to earn an aggregate annual net railway operating income equal to a fair return on the aggregate value of the railway property used in transportation. In 1933, the statute was changed so as to omit this definite requirement and to instruct the Commission to give due consideration, among other factors, to the effect of rates on the movement of traffic. This new provision has been interpreted by the Commission as a direction to consider many matters aside from transportation conditions in determining the reasonableness of rates, and to substitute its own judgment for the judgment of the railroads on the question of whether or not increased rates will yield increased revenue. This construction in effect puts the Commission in the position of business manager of the railroads, passing judgment upon the question of what rates will or will not promote the movement of traffic, which is essentially a matter for determination by those who are responsible for the management of the railroads. The Commission has no direct contact with the subject and can reach its conclusions only on the opinions expressed by witnesses before it; in many instances these witnesses represent the people who would be required to pay the increased rates. The railroad managements would not propose rates which they thought would appreciably reduce the volume of traffic on the railroads and, even if they should make such a mistake, they are the ones who must bear the responsibility for the results of railroad operation. The law should be amended so as to restore the 1920 direction to the Commission to regulate rates in such a manner as to yield a fair return upon railroad property devoted to the public service, and to eliminate the existing admonition that the Commission consider the effect of rates on the volume of traffic.

A number of other proposals have been advanced for increasing the earnings of the railroads legitimately, such as repeal of the so-called "land grants" which now give the Federal Government practically 50% reduction on a large volume of traffic, and repeal of the "long-and-short haul clause" of the Interstate Commerce Act. These, and other proposals, would be of substantial assistance to the railroads in their present struggle with unregulated and subsidized competition; but the most important single legislative step which should be taken at once is the restoration of the 1920 rate-making rule, which would give the railroads a chance to exercise their best judgment to increase their net railway operating income by such rates as the Commission might approve as reasonable.

Increased earnings have a direct bearing on increased operating efficiency. To take advantage of the economies offered by new devices and improvements it is necessary to attract capital, and that depends upon ability to pay interest. The rate of retirement of old equipment is to some extent dependent on the depreciation charges which earnings will stand. The railroads must earn more money before they can eliminate many unnecessary expenditures of this type.

Another class of unnecessary expenditures, of an unproductive character, is for separation of highway grade crossings, for the principal benefit of traffic on the highways; increasing the size of railroad bridge openings, for the benefit of traffic on waterways, and special assessments for municipal street paving, drainage, and other local improvements. Mention of such enforced contributions for structures and improvements of a local nature leads to the thought of the vast sums of money being exacted each year from the railroads for Federal, State, county, city, town, village, school, park, library, and other purposes. Railroad taxation is too large a subject for this kind of discussion. Of course, the railroads should contribute their fair proportion of the cost of Government, but it is fundamental that the burdens of taxation should be distributed equally. One striking inequality is the heavy taxes on railroad terminal facilities in contrast to tax free municipal barge terminals and airports.

Another cause of unnecessary expenditure is found in the rules and regulations respecting rates of pay and working conditions in railway service. The agreements with the railway labor organizations have not been adapted to changed conditions, and their application results in some instances in exorbitant payments and, in others, payments far greater than the industry can afford. "Make-work" laws, limiting length of trains, size of crews, etc., are of like character.

One of the few railroad questions upon which the writer seems to differ with Mr. Lavis is that of consolidation; perhaps the two views are not so divergent. Mr. Lavis is opposed to consolidation when carried to the extent of building up such large organizations that they lose the sense of personal management, and he expresses approval of reasonable competition in the railway field. With these general expressions the writer is in full agreement, although there might be a difference of opinion as to the precise number of consolidated systems. In England a little more than 20 000 miles of railroads were consolidated into four systems. In the United States approximately 240 000 miles of road were disposed of in eighteen systems in the final consolidation plan of the Commission. Reducing the number of railroads to about eighteen or twenty would eliminate a tremendous amount of over-head organization, would enable traffic to be concentrated on the most favorable routes, using the best parts of the several lines as they now exist, and would automatically bring about the most desirable type of co-ordination of terminals—that is, co-ordination in a few strong ownerships. The beneficial features of competition would be preserved and enhanced, because a relatively few strong roads, able and willing to give good service, would insure a higher quality of competition than could be obtained from too many lines, competing with each other and weakening each other by excessive competition, and unable to use their facilities to capacity. Capital costs would be reduced. All of the indispensable advantages of private operation would be preserved.

Of course, large-scale consolidations would reduce the number of railroad officers and employees. In England, provisions were made for their protection, and the railroads in this country now have the so-called Washington Agreement with the railroad Brotherhoods providing for payment of a "dismissal wage" in case of consolidations. Undoubtedly, some reasonable provision could be made to avoid turning any man out on the street. Although the cost of such provision might postpone for a few years the full economies to be derived from consolidation, the problem is not so large as might be imagined. Mr. Leslie Craven states[24] that if the railroads were consolidated into seven or eight major systems, it is probable that about 75 000 men would lose their jobs; whereas, from July, 1937, to June, 1938, railway employment decreased from 1 174 000 to 914 000, or by 260 000 men.

L. ALFRED JENNY,[25] M. AM. SOC. C. E. (by letter).—The railroad problem is a very live issue at present. The writer is in general agreement with Mr. Lavis' analysis of the situation and his conclusion that the railroads are, and will continue to be, the major transportation medium. Some national research bureau would be very valuable. Much could be accomplished by the use of lighter and more modern equipment. Certainly something must be done to save the railroad industry. The writer does not agree with some of Mr. Lavis' conclusions, however, or the solution he offers. He agrees with the general diagnosis, but disagrees on the cure.

Are Many of Our Railroads Over-capitalized?—Mr. Lavis maintains that the railroads of the United States are not over-capitalized, and he thinks it is not necessary to put many of them "through the wringer." There are many schools of thought on this subject, and it all depends upon the standard by which the capital structure is judged. If it is judged on the basis of valuation for certain periods, then many capital structures compare favorably; but it is not fair to stop there without also taking into consideration the past, present, and future potential earning power of the property.

Abundant examples are available of industrial plants built to meet increasing demands for their product, which could not even be duplicated to-day for the price paid originally, but which now have very little value, not from a physical point of view, but because they are being operated only at a fraction of their possible capacity, and because there appears little chance of operating fully again. These industrialists have long since taken their losses and have written off a very substantial portion of the original investment.

---

[24] "Railroads Under Pressure," by Leslie Craven, *Atlantic Monthly*, November, 1938.

[25] Cons. Engr. (L. Alfred Jenny & Co.), New York, N. Y.

The argument may be raised that one cannot compare an industrial plant with a railroad; perhaps not. The railroad picture is even worse, because the industrialist can close a part or all of his plant if need be, whereas the railroad cannot, and, therefore, should have a financial structure that will enable it to remain solvent in depression periods.

Railroads were built to meet what looked like an ever-increasing flow of traffic and in a period when competition from other forms of transportation was negligible. Now, with increasing competition, many of them cannot possibly hope to operate to a capacity sufficient to compensate properly all classes of investors. Many of these railroads have not even been able to pay interest charges on income bonds during good years, when there was very little other competition, to say nothing of payments on the preferred or common stock. In fact, there have been many bankruptcies even during prosperous years. The common stock has received improper consideration in many instances—a very unfair procedure.

If a railroad is properly capitalized it should be able to pay a fair return on all classes of securities (even on the common stock) during prosperous times. If it cannot do that, it is difficult to understand how one may claim that it was not over-capitalized, or that it was not necessary to reduce its capital structure to such an extent as to permit a reasonable return for all classes of security holders in good times. The Interstate Commerce Commission has stated that, in general, the railroads are not over-capitalized. The writer believes that this statement was based on the valuations; yet the Commission wants to reduce fixed obligations drastically; in many instances it has held that the common stock had no value and has recommended that these securities be eliminated from consideration in reorganization proceedings. If that is not evidence of over-capitalization, one may ask, "What is?" Many railroads are, in fact, over-capitalized and many of them must be put "through the wringer" in order to effect a cure and not merely a palliative which perpetuates a diseased body and even adds new complications. One of the fundamental difficulties of the carriers is that so many of them have been continually adding new security issues to meet new requirements and, instead of following a balanced program of cancellation when they became due, have resorted to the policy of refunding. Although many of them had no alternative, it has made their financial position increasingly precarious.

Added Federal Loans.—Mr. Lavis is in favor of Government credit and the making of Government loans to the carriers; and he states (see heading, "The Solution: Government to Furnish Capital and Credit to Railways"), "if the railroads are to avoid Government ownership and operation to which the President says he is opposed, there is little else that can be done." Here too there are many schools of thought; but one may ask seriously how it is expected to repay these loans, or even to pay interest on them, if no drastic measures are taken at the same time to revamp the entire industry and "put it on its feet." Under the circumstances, such loans will only add to the financial woes of the carriers and help to force early Government ownership, the very effect Mr. Lavis hopes to avoid. It is probably true that the Government will have to extend credit to the railroads and make substantial loans to permit rehabilitation, but that should not be done without, at the same time, setting up proper machinery for bringing about a reconstitution of these properties and a sound national plan of co-ordination and correlation of all forms of transportation.

Deferred Maintenance.—Mr. Lavis states that the deferred maintenance at the end of 1937 was estimated to be approximately one billion dollars. The writer believes that it was more than that, based upon a study in which he compared the maintenance costs of the five years, 1932–1936, inclusive, with those of the seven years, 1925–1931, inclusive.

As the cost per equated ton-mile was deemed to offer the best relative comparison, that method was used. It is fully appreciated, however, that some labor-saving devices have been installed in recent years which did not exist during the late twenties, and that some processes have been developed for extending the lives of rails, ties, etc., and that these have somewhat reduced the cost of comparable maintenance. By making a direct comparison between say, 1925–1929 and 1932–1936, the resultant value, therefore, would tend to show a slightly greater sum for deferred maintenance than actually existed. In order to be conservative, and in some way to compensate for this condition, the first two depression years, 1930 and 1931, were added to the base period. This introduced an equalization factor of about 10%, or, in other words, the resultant value, covering all maintenance expenditures including materials, etc., is about 10% less than it would be if the years 1925–1929 were used as the base period.

The result of that study, and on the basis outlined, is shown in Table 4. The total under-maintenance on Class 1 railroads, alone, for the five depression years, 1932–1936, has reached the staggering sum of nearly 900 million dollars and if Class 2 and 3 railroads, and switching and terminal companies are added, the total will be much greater. If 1937 and 1938 are added, it is believed that the total for deferred maintenance will be nearly 1½ billion dollars.

TABLE 4.—STUDY OF DEFERRED MAINTENANCE, CLASS 1 RAILROADS

MAINTENANCE OF:	(a) UNDER-MAINTENANCE, IN MILLS PER EQUATED TON-MILE				(b) TOTAL FOR THE FIVE YEARS, 1932 TO 1936, INCLUSIVE, IN DOLLARS			
(Districts)	Eastern	Southern	Western	Total	Eastern	Southern	Western	Total
Way and structure	0.42	0.33	0.36	0.380	283 400 000	114 300 000	191 800 000	589 500 000
Equipment	0.27	0.14	0.11	0.185	182 100 000	48 500 000	58 600 000	289 200 000
Total	....	....	....	.....	465 500 000	162 800 000	250 400 000	878 700 000

If the deferred maintenance was estimated to be about 1 billion dollars at the end of 1937, it would probably be about 1⅛ billion dollars to-day (1939) on that basis. Whether it was that value, or 1½ billion dollars, or some intermediate value, is no doubt a question of judgment. The important question is, "How is it to be met?" No one can give the answer at this time. One thing is certain: It will represent a staggering sum, a "millstone around the necks" of these carriers which, for an indefinite period, will prevent them from enjoying even a relative economic freedom, so essential to the up-building and stabilization of that industry, and which will greatly retard the rehabilitation of these properties.

When it is considered that some of these railroads have maintained their properties along a higher standard than others, it must be obvious that some carriers will be found to be below the average standard of the district. Such a continued under-maintenance is certain to become dangerous if prompt measures are not taken to obtain an early remedy.

It must be obvious from this that maintenance costs in the future, at least for many years to come, will be more, instead of less, than in the past, and that if any operating savings are to be made they must be made in other ways than at the expense of proper and adequate maintenance.

Labor.—The United States has not been immune from the surges of varying philosophies going in one direction or another, and there has been a considerable change in attitude, particularly with regard to labor problems. Some call it the emancipation of labor; others call it by a less euphemistic name. Whatever it may be called, it is something to conjure with. It cannot be disregarded. The proper thing to do would seem to be to recognize its existence and assist in directing it along sound, equitable, and democratic lines.

In reviewing the railroad situation the labor problem must therefore be considered seriously, particularly in its effect upon possible future net earnings. During low traffic periods in the past, the railroads were able to reduce wages and thus correspondingly reduce operating costs, resulting in a more uniform ratio between income and outgo. All statistics, including maintenance, therefore, bear some relation to the prosperity of the carrier. It seems doubtful if such a procedure can be followed in the future.

The 1938 decision in regard to the reduction of 15% in railway wages is a "shining example" of this changed philosophy. No one can deny that this decision will have a tremendous and far-reaching effect upon the future of the railroad industry. Only a few years ago, and under similar economic duress, railway labor would have been almost certain to lose, or at best effect a compromise. Failure to recognize this condition can only result in disappointment later.

The railroads had estimated a net saving of about 250 million dollars annually with the 15% wage reduction they had asked for, and they stated frankly that, if such a reduction were not made, serious consequences would result. No reduction has been made, and there appears to be little likelihood that any will be made, of sufficient importance to have any material effect upon the net operating returns of the carriers.

Railroads must be prepared, therefore, to effect important savings in other ways because the carriers cannot continue to function properly under the existing heavy burden of expenses. Some people have suggested a profit-sharing plan for labor as a possible solution. It would have the effect of providing an equalizing factor, fluctuating with the prosperity of the carrier. It may well be that a solution along these lines could be effected which would establish a minimum fixed return for both capital and labor, and permit labor to share with the stockholder the fruits of a more abundant day.

The Problem.—The problem that confronts the nation is much broader and much more deeply rooted than what is commonly referred to as the "railroad problem." In order to grasp this fact fully it is necessary to review some of the underlying factors briefly. With few exceptions the railroads were built with private capital. They enjoyed a monopoly on transportation and attracted great sums of money for new construction to meet an expanding trade. Although the inland waterways, developed at public expense, had long predated the railroads, they offered no formidable competition, particularly with reference to the growing transcontinental traffic. Then the Government built the Panama Canal, at public expense, and this project detracted great tonnages from the transcontinental railroads of the United States. Not only is that tonnage lost, but the diversion is increasing.

New ports were established, at public expense, along the Gulf of Mexico, and much of the rail tonnage, particularly between Texas and Louisiana and the Eastern seaboard, is now (1939) handled by coastwise shipping, in which field competition is increasing.

Pipe lines were then built, taking the oil away from the railroads. In addition to losing the oil business this development has had the effect of substituting oil for coal in many fields. As coal is one of the most profitable carrier commodities, this trend has reduced railroad revenues seriously.

Large-scale highway developments were made necessary by the introduction of the automobile. They were built at public expense, and passenger and freight-carrying vehicles, both public and private, were permitted to operate over them in competition with the railroads. This agency has proved to be by far the most serious competitor of the carriers. In addition, it has made necessary very large railroad expenditures for grade-crossing eliminations, thus not only reducing carrier income, but increasing outgo.

Finally, there has been a great development in the air industry. Most of the airports were built by municipalities, again at public expense, and since no traffic arteries had to be built, with perhaps the exception of beacons, the airplane too began to compete over public facilities.

The truck and the bus are, in fact, making such inroads upon the carriers, in so far as traffic within a radius of a few hundred miles is concerned, as to remove, completely, any necessity for demanding, in addition to that, competition between the carriers. The airplane, on the other hand, is making heavy inroads on the long-distance passenger and preferred merchandise traffic, creating a natural competition for that class of business. The coastwise shipping is handling increasing tonnages of a very desirable class of bulk transcontinental traffic and in recent years has cut heavily into the profitable refrigerator business, thus creating a natural competition for that class of business.

All of the aforementioned forms of competition are here to stay. The competition sought in early legislation has been largely, if not completely, supplanted by these other forms of competition, reducing the railroads to the handling of such mass transportation as can still be performed best by them, and which, no doubt, will continue to be handled by them.

Here again, however, other factors are working against the railroads. The nation has witnessed a formidable movement, decentralizing important industries and establishing manufacturing plants close to the sources of supply, thus greatly and permanently reducing the profitable long-distance railroad shipments of raw materials and finished products, previously enjoyed by the railroads. Not only has this seriously reduced railroad traffic, but a considerable percentage of the traffic that would remain has been taken away by the trucks.

All of these elements must be considered seriously, entirely apart from the present reduction in net railroad revenues due to a reduced volume of business because of the depression, lower rates, and higher wages. The depression is only one of many elements contributing to the present plight of the railroads which has been accentuated by top-heavy financial structures. It can be understood, therefore, that, even with a return to normal times, the railroads will not get even a relative percentage of their former tonnages.

If the railroads were to be placed on a parity with these other forms of transportation in so far as facility ownership is concerned, the public would have to provide either railroad lines or terminals, or both; and it would have to permit private operation over these facilities. Under effective consolidations it would be possible, at least, to have new consolidated terminal facilities owned by the public and leased to the carriers for private operation. This improvement would save the railroads large sums annually and would still permit the continuation of the principle of private ownership and operation.

It has been suggested that transportation companies be organized to supply all forms of transportation. If competition is desired it would be most logical to maintain it under this type of organization, as the present and effective types of competition would be removed. However, there is considerable opposition to this type of organization, particularly by the present competitors of the railroads who would lose their identity.

It must be apparent that the problem which confronts the transportation industry, and which must be solved effectively and courageously, is far greater than the commonly accepted and circumscribed railroad problem. The scope and character of the solution required is so far beyond the control of the railroads that it is impossible for them to attempt a solution alone. Co-ordination and correlation of all forms of transportation, wherein each can labor with a certain degree of freedom within its own sphere, are essential to a sound solution. That requires centralized and authoritative direction and impartial administration.

The proper procedure is to recognize all the foregoing basic elements and prepare a sound, comprehensive plan in the interest of the transportation industry as a whole. The centralized authority could be either: (1) A new Federal department under a Secretary of Transportation; or (2) a Federal Transportation Authority, whose duty it would be to effect a national policy of transportation looking toward a truly co-ordinated and correlated system of transportation for both civil and military purposes, and to promote a plan of sound and all-inclusive railroad consolidation.

The term "military purposes" is included because, although much progress has been made in industrial mobilization for war, nothing has been done to plan and organize properly the transportation system, which is the back-bone of all military operations. The railroads should be prepared to superimpose upon civilian traffic, on a given day, the transportation of vast quantities of raw materials and the finished products of these industrial plants and of the military forces and equipment, without causing a serious disarrangement of civil transportation requirements, or the possible collapse of the entire system. No other major country is as unprepared as the United States in this respect.

Under the aforementioned plan all Federal regulatory functions, covering all fields of transportation, could then be entrusted to the Interstate Commerce Commission, with such added facilities and authority as may be needed.

The writer's views on this general subject, and particularly on the creation of a central Authority, are shared by many outstanding men in different walks of life. W. J. Wilgus, Hon. M. Am. Soc. C. E., has frequently recommended[26] such a central Authority as the only way to cope with this situation adequately. In the report of the Coolidge-Smith Committee (1933), former Governor Alfred E. Smith recommended the creation of a Department of Transportation in Washington, D. C. Similar opinions have been advanced forcefully by Mr. W. M. W. Splawn, Chairman of the Interstate Commerce Commission[27] and (from a legal view) Mr. Leslie Craven, who was for many years a railroad attorney representing various carriers in Washington.[28] This problem was well on the road to a solution when the railroads frustrated their own salvation by having the office of Railroad Co-ordinator abolished.

Mr. Lavis seems to consider centralized planning for the improvement of this industry an un-American procedure—one of governmental paternalism. If the railroads could solve this problem without some centralized direction many would no doubt agree with Mr. Lavis in principle, but since it must be obvious that the carriers cannot do so, it becomes anything but an un-American procedure to help put this industry "on its feet" in the interest of the industry itself and the country at large. Transportation no longer can be viewed as an individual problem, or a private monopoly, because it has long since ceased to be that. This problem must be viewed in its broadest sense, with the realization that one of the fundamental factors, essential to sound and intelligent planning, is unbiased and objective thinking, freed from selfish consideration. It must be solved in the interest of the transportation industry as a whole, not merely the railroads, and the economic well-being of the country in general.

Under the aforementioned circumstances, and restricting comments to the railroad field, with about one-third of the railroad mileage in receivership and with huge sums already advanced to them by the Government, it is difficult to understand how any one can expect to ward off Government ownership of the railroads unless some sound plan of general consolidation is advanced. In fact, some of the foremost engineers, and even railroad and fiduciary officials, seem to see no other escape than to resort to Government ownership. Competition will probably be restricted or completely removed in certain areas, under Government ownership, unless some effective plan can be devised for private operation of publicly-owned systems, outside of political influence.

[27] Report of the Fiftieth Annual Convention of the National Association of Railroad and Utility Commissioners, New Orleans, La., November 15–18, 1938, *Railway Age*, November 26, 1938, p. 776.

[28] *Atlantic Monthly*, December, 1938, p. 767.

Railroad Consolidation.—In order to establish a co-ordinated and correlated system of transportation in this country it is essential that each type of transportation, or each system, be given a certain sphere of activity which will enable it to "stand on its own feet." What must be done to accomplish this with the railroads? There is general agreement that one of the fundamental requirements is railroad consolidation.

Apparently, Mr. Lavis is in favor of permitting the carriers to make such voluntary consolidations as they may care to make without regard to some national plan. He believes in maintaining strong competition between the carriers and considers that as creating "a healthy state for an industry such as railroad transportation" (heading "Suggested Remedies: Competition"). Again it must be said that there are many different schools of thought on this subject and it would seem most important to give this matter serious consideration.

As stated previously herein, maintenance expenses will be relatively higher in the future, and it is most unlikely that railroad wages will be reduced, or at least sufficiently to have any appreciable effect upon the net income of the carriers. Therefore, railroads must look elsewhere for important savings.

Such consolidations as have been made in the past have not helped to relieve those carriers that are most in need of assistance, because the strong roads are unwilling to merge with the weak ones. The ultimate result of such a policy will be that the nation will find itself with many poor, broken-down railroads on its hands, which nobody wants, yet which are necessary to serve economic needs. What will then happen to these roads? The result is certain to be more chaos and more demands for Federal help, all at the expense of the taxpayer. It is not likely that the Government, irrespective of who may be in power, will continue to support these roads without demanding a sound reconstitution of the industry as a whole, and the absorption of the weak by the strong, along some kind of national plan.

There are several reasons why little progress has been made in the past by the railroads, or can be made by them in the future, if the problem of consolidation is left in their hands without some form of compulsion following a prescribed pattern.

There are too many divergent interests to be considered, which, if not directed by an impartial outside Authority, will result in disagreement and unsound consolidations. Many high railroad officials would find their positions abolished, and it is only natural for them not to expedite, or even belittle, effective consolidations, although they well know that the industry as a whole would be greatly benefited. Finally, present laws are inadequate to permit really effective consolidations, because they are based upon the predicate that strong competition be maintained, as between the carriers.

With the many forms of natural competition established, as outlined previously herein, there would seem to be no reason for demanding, in addition, competition between the railroads themselves, except possibly between Mid-Western points and the seaboard. The regions served by the railroads, and the country at large, would be served to much better advantage by removing restrictions as to competition between the carriers and permitting regional consolidations of privately-owned and privately-operated systems. The entire country benefits from a stable transportation industry.

In view of the many competing forms of transportation it must be obvious that the railroad plant, designed and built as the exclusive transport agency, is now greatly in excess of the needs of the people. Some of the facilities can, and should be, abandoned. That can be done under a proper and all-inclusive plan of consolidation. If the railroads do not so consolidate, it will be impossible to abandon a large number of the weak lines which, unfortunately, are essential to the economic existence of many regions.

If the present policy of voluntary consolidations is continued, it must be obvious that a fight for the "survival of the fittest" will result, which neither the railroads, nor the country as a whole, can afford to do. It would result in profits by the few and a "falling by the wayside" of the many, unless, of course, they are saved by the Government; but that is not sound planning, not sound engineering. It would seem far better to plan a sound solution than to sit back and await the inevitable, with resultant chaos.

With increased costs, and increasing competition, railroads of the United States, particularly the weak ones, would have to ask for rate increases at a time when a reduction in rates would have a most wholesome and far-reaching effect upon the entire economic structure of the country.

Where it becomes necessary to abandon certain properties because of the obsolescence of the plant, administrators must also take care of the consequent obsolescence of man-power. If it is economically desirable to abandon certain lines, the carrier can give such labor protection as may be necessary and fair to all. That should be mandatory. It would not be a permanent burden.

In discussing possible losses of labor in connection with such an all-inclusive program it should be stated that it will be necessary to create many new and important consolidated railroad facilities, totaling many hundred millions of dollars, particularly in terminal districts, giving work to scores of thousands of workmen all over the country and greatly benefiting all basic industries. This will largely, if not completely, offset losses of labor due to abandonments which, after all, will represent only a nominal percentage of the total railroad mileage.

It has been recommended recently that the railroads be relieved of certain obligations so that they can spend these savings, amounting to many hundred millions of dollars, for much needed improvements. As some of that money would no doubt be wasted with a proper plan of consolidation, which is certain to be adopted ultimately, it would seem prudent to proceed first with effective consolidations and then make such adequate improvements as will serve such a permanent and co-ordinated railroad plant.

Under the foregoing circumstances it would seem futile to expect any worth-while solution, unless some central and neutral authority is set up with power to compel proper consolidations. Such Federal Authority must establish the general pattern, but the railroads themselves should do much of the detail work of effectuating such a plan.

A Possible Solution.—Convinced that the greatest savings could be made under the regional type of consolidation, the writer made a study of consolidating the railroads into six regional systems. That study is presented herein, not as an unalterable plan, but merely to show what could be accomplished under the type of plan recommended in opposition to Mr. Lavis' position with reference to consolidations.

Since many regions have problems peculiarly their own, it is not difficult to group these railroads in such a way as to have each region covered by such a system. Thus the different carriers could be grouped effectively into North Eastern, Central Eastern, South Eastern, North Western, Central Western, and South Western systems, herein referred to as Systems I, II, III, IV, V, and VI, respectively. All traffic within these systems would be handled by that one system, but, as stated before, there should be competition in a larger sense, such as providing, for instance, two competing lines between Mid-Western centers and the seaboard or between important, interior, industrial centers. To establish such competition it will be necessary to provide certain "bridge lines" reaching from one system into such important centers of another system. This principle has been followed herein in the allocation of railroads to the various systems. The ten principal Class 1 railroads tentatively assigned to each of the six systems are as follows:

I.—North Eastern System: New York Central; Illinois Central; Wabash; Pere Marquette; Erie; Boston and Maine; New York, Chicago and St. Louis; Maine Central; Delaware, Lackawanna and Western; and Alton Railroads.

II.—Central Eastern System: Pennsylvania; Baltimore and Ohio; Louisville and Nashville; Chesapeake and Ohio; Reading; New York, New Haven and Hartford; Lehigh Valley; Western Maryland; Virginian; and Long Island Railroads.

III.—South Eastern System: Southern; Norfolk and Western; Atlantic Coast Line; Seaboard Air Line; Central of Georgia; Florida East Coast; Yazoo and Mississippi Valley; Mobile and Ohio; Nashville, Chattanooga and St. Louis; and Gulf, Mobile and Northern Railroads.

IV.—North Western System: Chicago, Milwaukee, St. Paul and Pacific; Chicago and North Western; Great Northern; Northern Pacific; Chicago, St. Paul, Minneapolis and Omaha; Minneapolis and St. Louis; Chicago Great Western; Spokane, Portland and Seattle; Duluth, Missabe and Northern; and, Green Bay and Western Railroads.

V.—Central Western System: Atchison, Topeka and Santa Fe; Union Pacific; Chicago, Burlington and Quincy; Chicago, Rock Island and Pacific; Denver and Rio Grande Western; Western Pacific; Colorado and Southern; Fort Worth and Denver City; Chicago, Rock Island and Gulf; and Northwestern Pacific Railroads.

VI.—South Western System: Southern Pacific; Missouri Pacific; St. Louis and San Francisco; Texas and New Orleans; Missouri-Kansas-Texas; St. Louis Southwestern; Kansas City Southern; Louisiana and Arkansas; Missouri and Arkansas; and Midland Valley Railroads.

No doubt, a further study would reveal the desirability of certain reallocations between the foregoing systems. For instance, System I has no

access to Baltimore, Md. Either the New York, New Haven and Hartford Railroad may be allocated to System I or that system may be given one of the coal carriers to Baltimore. Such possibilities, however, do not change the principle of regional systems. The regions covered by these systems are shown in Fig. 1.

The total miles of road, the investment in road and equipment, long-term debt, income available for fixed charges, and the fixed charges for each of the proposed six systems, as of the Interstate Commerce Commission Report for 1936, are shown in Table 5. Canadian or Mexican owned roads in the United States are not included.

TABLE 5.—MILEAGES, INVESTMENT, INCOME AND FIXED CHARGES OF THE PROPOSED SIX GREAT SYSTEMS, IN MILLIONS OF DOLLARS (Exclusive of Foreign-Owned Roads)

System	Miles (1)	Investment in road and equipment (2)	Long-term debt (3)	Income available for fixed charges (4)	Fixed charges (5)
I	41 997	4 109.72	2 474.61	200.35	158.05
II	36 400	4 695.78	2 822.88	305.17	192.65
III	36 098	2 269.87	1 064.76	96.50	62.46
IV	43 633	2 922.74	1 658.71	80.61	78.32
V	51 467	3 294.82	1 268.43	91.47	74.76
VI	42 587	2 617.27	1 780.07	104.27	109.92
Total	252 182	19 910.20	11 069.46	878.37	676.16

Table 5 includes all of Classes I, II, III, and switching and terminal railroads. Income available for fixed charges (Column (4), Table 5) was not reported for Classes II, III, and switching and terminal roads; net railway operating income has been used for these cases.

It is practically impossible to have these systems so created as to give each the same mileage and the same income. It may be seen, however, that a fair balance has been achieved in this limited study.

With this plan, and even with many existing top-heavy financial structures and consequent heavy fixed charges, the fixed charges would have been earned in 1936, 1.27 times for System I, 1.58 times for System II, 1.54 times for System III, 1.03 times for System IV, 1.22 times for System V, and 0.95 times for System VI. In every one of these regions there are railroads under reorganization. With these in effect a much more favorable ratio would result.

The study would seem to indicate clearly that the main purpose (namely the establishment of a fair earnings balance) could be obtained which would stabilize the industry and re-establish credit which is so sadly lacking to-day. Such a plan would do effectively what the Recapture Act failed to do.

In addition to this stabilization very substantial operating savings will result from the pooling of equipment and the consolidation of operations within these systems. What these savings will be, of course, is pure speculation based upon hypotheses which, in practice, may have to be materially modified. They have been variously estimated at between 250 and 750 million dollars per annum, based upon depression traffic. Even the lowest value would be a worth-while inducement for making a change, but the net result is certain to be more nearly 500 million dollars. In addition to this it should be borne in mind that the securities of such a system, with a modified capital structure, would be nearly as safe as Government securities and could be marketed at much lower interest rates than are paid at present. This arrangement would naturally further reduce expenses and still further strengthen the financial position of these systems.

Mr. Lavis seems to be of the opinion that in such large organizations it would not be possible to maintain personal contact. In so far as straight distances are concerned these new systems would be no different from the present large systems reaching from the Mississippi River to either the Eastern or Western seaboard. Instead of one railroad ribbon across this distance there would be several. This will necessitate the creation of regional managers who certainly would be able to maintain a closer contact than is now possible with some of the existing carriers.

Effectuation of Such a Plan.—Within a relatively short period of time, the Federal Authority could prepare a tentative plan and then allow the railroads, say, 6 months or 1 yr, within which to offer modifications and to submit a plan of organization, abandonments, etc. In the meantime, the carriers could appoint some Board of Managers, composed of one member from each road to be consolidated, whose duty it would be to co-operate with the Authority.

After the aforementioned modifications have been considered by the Authority, it could then issue a general plan and order the Board of Managers to manage these properties as consolidated systems for a trial period of, say, 5 yr. This will allow further modifications to be made in the plan and will mark the beginning of 10-yr program of abandonments. These should be spread over a considerable period of years.

After the 5-yr period has elapsed the Authority could then issue its final plan and order the election of system officers and the establishment of these great systems. The Authority would also prepare a financial plan indicating the amount of new system securities it deems proper to allocate to the then existing individual securities. In this allocation weight might be given to: (1) The valuation; (2) the last 5 yr of earnings as an independent carrier; (3) the first 5 yr of system earnings contribution; and (4) other special merits of the respective carriers.

Under such a procedure an immediate beginning could be made and ample time would be allowed for the consideration of varied interests. These six great systems should be organized under a Federal charter as national systems.

Other Considerations.—In addition to the consolidation and rate-equalization problems, consideration should also be given to legislation establishing a uniform system of railroad taxation based upon the dictates of national economy and the welfare of the industry, and a uniform system or policy with reference to amounts to be paid by the railroads for grade-crossing eliminations. Numerous other measures, intended to give immediate relief and which have already been recommended by various bodies, should naturally be adopted in addition to the long-term program outlined herein.

Conclusion.—The railroads must have new capital to build up these properties. The poor roads, which are most in need of new capital, cannot get it except at exorbitant rates, because the investor, whether it be an individual or a fiduciary institution, is afraid to risk his money.

It is necessary to restore confidence in the industry as a whole. That can best be done by a scientific grouping of poor and prosperous roads within certain regions, with resultant important savings, and the consequent balancing and equalization of resources. It cannot be done by making only a few minor consolidations of desirable properties, as would be the case if left to the railroads for solution. An impartial Federal Authority must be established with power to compel a sound solution in the interest of the transportation industry as a whole and the country in general.

WILLIAM J. CUNNINGHAM,[29] ESQ. (by letter).—A well-rounded and concise summary of the present rail situation is presented in this interesting paper. The writer feels, however, that Mr. Lavis has placeed too much emphasis upon what he calls "fundamental defects in governmental regulation" (heading, "Synopsis"). He is inclined to attribute the difficulties more to regulation than to the loss of traffic because of the general depression. The writer believes that the depression accounts for much the greater part of the difficulties.

The statement that "It has been shown time and time again that the railroads are not over-capitalized" (heading, "Needs of the Railroads: Railroad Capitalization") needs greater amplification than is given in the paper. It is true that they are not over-capitalized from the viewpoint of dollars invested in transportation facilities, but they are over-capitalized from the viewpoint of dollars invested in facilities that are now used and useful. A substantial part of railroad capital is in useless branch lines, needless multiple running tracks, unused sidings, facilities designed for earlier days with shorter train runs and different characteristics of traffic, and duplicate terminals and other facilities. There must be a realistic recognition of the high degree of obsolescence in investment and capitalization written down to conform to the investment in productive property. Holding these views, it is obvious that the writer does not agree with the assertion that "There seems to be no valid argument against maintaining the present financial structures intact" (heading, "The Solution").

Greater emphasis should have been placed upon the need of organized and centralized research. The single paragraph on that subject is not consistent with the statement in the Synopsis that "special stress" is laid on that need.

In the discussion of the causes which have adversely affected the volume of railroad freight business, specific mention should have been made of technological advancements which have made possible the production of more units of finished product for a given volume of raw material. The substantial improvement in the efficiency of fuel consumption on locomotives, for example, has had the result of reducing, correspondingly, the volume of railroad-borne coal for railroad use.

[29] James J. Hill Professor of Transportation, Harvard Univ., Boston, Mass.

S. R. TRUESDELL,[30] ASSOC. M. AM. SOC. C. E. (by letter).—Statistics presented by Mr. Lavis referring to the relative amount of transportation in the United States might have been somewhat more comprehensive as to motor transport if he had used data secured by the U. S. Department of Commerce in its Motor Transport Survey of 1935. This survey showed that common-carrier motor trucks earned \$531 000 000, and motor buses \$168 000 000, a total of \$699 000 000, which with the private truck operations would make a very much more formidable showing than Professor Worley's estimate for 1932. In fact, the Bureau of Economic Research of the Department of Commerce has made estimates from year to year of the earnings of all types of transportation, which show the following distribution for 1936, in millions of dollars:

Type of transportation	Millions of dollars
Steam railroads	2 787
Motor transport	1 274
Electric railway	436
Water transportation	535
Air and pipe line	97
Total	5 129

On this basis motor transport earned 25% of the total transportation revenue in the United States for 1936. Similar data in 1929 showed motor transport with \$1 194 000 000, or 17.5% of the total transportation bill of \$6 847 000 000 in that year. As the actual total in 1936 should have been about \$6 000 000 000 on the basis of the index of business activity, the motor trucks have made heavy inroads into railroad traffic during the depression. However, if total traffic had increased in this period in continuation of the trends existing from 1910 to 1929, the increase in truck traffic would have been comparatively unnoticed.

In using the very heavy traffic on the Pennsylvania Railroad between Pittsburgh, Pa., and Altoona, Pa., to illustrate the impossibility of handling rail freight by trucks, Mr. Lavis forgets the tremendous mileage of railroad in the territory west of the Mississippi River which has less than 500 tons per day. It is on these lines that the cost of rail transportation and over-head has risen to 3 cents and 4 cents per ton mile, and thus into the economic realm of the motor truck, which is not 5 cents to 7 cents per ton mile, as cited by Mr. Lavis, but more nearly 3 cents. (Statistics were submitted to the Interstate Commerce Commission by thirteen typical truck operators, in the matter of "Increase of rates in Central Motor Freight Territory, 1937" showing approximately 625 000 000 ton miles costing \$19 000 000 or 3 cents per ton mile.) The railroad rate on such traffic is probably only 1.5 cents to 2 cents per ton mile so that truck substitution, which seems inevitable, will be more expensive. The uneconomic and unrecognized result of such transitions is the scrapping of valuable tracks and rights of way for the intangible values represented by

---

[30] Special Asst., President's Office, C. & N. Ry., Chicago, Ill.

"foot-loose" trucking operators; and this is a result of frozen rates due to overzealous regulation combined with unreasonable burdens of cost for labor and taxes. Some more modest type of rail motive power could easily accomplish the service needed at a lower cost, provided encouragement could be given to the rail management by relief from taxes, full crew laws, labor agreements, and out-of-date tariffs. Otherwise, the people in the communities served by the rail branch lines will pay increased sums for the transportation of coal, lumber, feed, gasoline, cement, and other necessary bulk products, or they will move away. In most territories affected by rail abandonments both of these contingencies are now happening.

If, through this process of erosion of the feeder rail lines, the railroad main lines are gradually deprived of traffic and, in turn, are compelled to raise rates from the present unprofitable 1 cent per ton mile, where will the process end? Furthermore, are even such apparently essential railroads as the Pennsylvania between Pittsburgh and Altoona safe? In each case in the past, the same conditions were present, the same slow attrition, the same support by regulation to prevent monopoly, and the same results eliminating the stages and the wagon transport of the 1800's, the canals of the 1830's, and now the railroads. Unless this process is to be arrested by release from anti-monopoly regulation, taxes, unreasonable labor provisions, and restrictive rate legislation, no railroad is safe from this uneconomical and artifically fostered process of change.

In regard to Mr. Lavis' paper, some reference is made, or implied, as to the extent of unremunerative capital expenditures since 1920. Mr. Eastman also has referred to this at times as an element for criticism. However, this is only a natural effort of a threatened industry to hold or improve its product in the face of dangerous competition. It would be the same in the case of two competing automobile manufacturers—new plants, new presses, new materials, without one dollar added to profits. If the effort were tardy or insufficient, as in the case of the railroads, there would be an absolute loss or decrease in profits with nothing to show for the capital invested. It is true that some of the expenditures for heavier locomotives, rail, and bridges seem foolish in the light of present facts; but they should be unquestioned as necessary in view of the strife for lower costs to keep the railroad systems solvent. Present-day speeds, quoted by Mr. Lavis as 40 to 50 miles per hr to satisfy the present "hand-to-mouth" merchandising, have probably doubled the costs of the tonnage trains of yesterday at 15 miles per hr; yet eminent economists have repeatedly justified the unit of gross ton miles per train hour (dependent largely on speed) as a measure of railroad efficiency. In the West the longest and most round-about rail lines have the highest "efficiency" in gross ton miles per train hour, and the least profitable results.

This paper has delved deeply and most intelligently into the ills of the railroads. The writer does not want to detract a bit from its value, which is great. He is almost ready to agree that the railroads are going backward; but it is not of their own volition. Railroad morale is very low. Under the stress of straitened circumstances research in both methods and materials is almost nil; and, by and large, the cause for this condition (which is destroying the largest and at one time the most efficient American industry) is as much from without as from within. It speaks well that there is still continued fighting effort from managements that have been so harassed.

David A. Molitor,[31] M. Am. Soc. C. E. (by letter).—This paper contains a most valuable presentation of the transportation facilities of the United States and deals comprehensively with the problems confronting each class of service. It emphasizes the fact that defects in governmental regulation are responsible for the grave financial difficulties of the railways, and that there should be better co-ordination of all transportation facilities. Finally, it stresses the fact that direct Government aid, like that now being extended to highways, waterways, and airways, should also be provided for the railways.

Informed persons will agree with most of these statements, but when it is proposed to extend Government aid to the railways, much will depend on the particular form in which it is given, whether by an out-right grant, by subsidy, or by an extension of credit; and also, what returns or guarantee should be given to the Government for such aid as may be granted by Congress.

In the case of the highways, the State and National Governments all collect special taxes on gasoline and for owning and operating motor vehicles so that highway construction and maintenance are being paid for by those using the highways. However, the highways belong to all the people, which means the Government, and those contributing the money therefore, have no vested rights in the property.

The natural waterways, in general, were made navigable by improvements and are kept usable by work done under Congressional appropriations paid from any funds in the Treasury. Any individual or corporation owning a boat can enjoy the free use of the national waterways; but again, the users have no vested rights in the property provided by the Government with money from the people. The improvement of the channels through the Great Lakes is the most extensive system in the United States and is not now, nor ever was, undertaken to serve any other purpose than that of navigation for both freight and passengers. In only one or two instances, such as the Tennessee Valley Authority, has flood control and power development been an important factor.

The airways have enjoyed the most generous treatment by the Government since they have been given subsidies toward operating expenses and generally have no monetary investments except in flying equipment.

The case of the railways differs in many respects from that of the other three facilities. It is now (1939) being proposed to place them in a position to partake in some measure of Government aid and thereby correct the inequalities which supposedly exist regarding their ownership, maintenance, and operation when compared with the others.

The railways enjoy no direct Government aid at present, although they carry the mails and considerable Government freight. In most States they pay a property tax similar to private land owners. According to the author, their total property investment in 1920 was about 19 billion dollars to which more than 6 billion dollars was added during the next twelve years, making a total of more than 25 billion dollars in 1932. In Table 2, the net operating income for 1932 is given with the annual rate of return on the capital invested, from which it appears that this capital sum was only slightly more than 7 billion dollars. How much of the remaining 18 billion represents property value? How was it acquired and who owns it at present?

---

[31] Cons. Engr., Harlingen, Texas. Mr. Molitor died September 8, 1939.

Many of the railways received land grants representing enough value to finance their construction with the aid of borrowed money from private investors.

Until about 1920, the railways were in practical control of all transportation business except between such terminals as were also served by the waterways. Their practices were such that they were declared common carriers under control and regulation by the Interstate Commerce Commission as a protection to the public against unfair practices.

The quarrel between the waterways and railways is an old one in which the latter were generally the aggressors. They fought the Panama Canal project for years until there came into the presidency a Theodore Roosevelt, who was big enough to subdue this propaganda and launch the undertaking. The Mississippi River improvement is another case in which a once prosperous water transportation was driven out of business but not with any great benefit to the railways, which were not properly equipped to carry cheap bulk freight.

A case in point to the contrary is the present spectacle of the St. Lawrence-Great Lakes Waterway, for which no one of sufficient stature has yet appeared who could settle the quarrel and subdue the opposition in Congress. It is regrettable that the power development was brought into the "squabble," but the navigation improvement must come sometime, and when the finances of the railways become sufficiently depleted on propaganda, perhaps they will spend what funds may remain on "putting their own house in order."

As long as business was good and money plentiful, due largely to low wages paid to operating employees generally, the railways could afford to fight everybody, including City, State, and National Governments, to maintain supremacy in the transportation field. They could do this and yet pay large dividends to stockholders and high salaries to officials. Then came the war period 1914–20, with the railways enjoying a virtual monopoly, but underequipped for the huge increase in business, so that with Government control and funds the wheels were kept in motion with sufficient new equipment to handle the heavy traffic, which continued to overtax the railways until about 1926.

The diversion of business to the highways, both passenger and freight, rapidly increased after about 1920, and, with the depression years 1932–38, caused the present surplus of transportation facilities on the part of the railways, while the highways were becoming busier each year.

During recent years the railways have been unable to compete with motor transportation both in kind and cost of service. It is doubtful whether any appreciable amount of the diverted business can ever be recaptured by a highly modernized railway equipment because of the greater convenience and house-to-house service afforded by motor for both freight and passengers, even at comparable rates.

Since 1928 the writer has traveled 75 000 miles by automobile and had his household goods moved 2 900 miles (including a single move of 1 900 miles) by motor van, all because of the superior efficiency and cheapness of this service. In short, he was prevented from using the railways because of the greater cost involved, their lack of house-to-house service, and loss of time due to poor schedules or infrequent service. The great majority of the traveling public is probably doing the same things for the same reasons.

The existence or non-existence of the railways of the future will hinge on "the survival of the fittest" as has already been the case with respect to interurban railways and some city street-car systems.

Big and little business has sought and found economies in freight costs, as the author mentions, which means a permanent loss to the railways. In their ambition to retrieve some of their lost business and to combat public dissatisfaction, the railways have gone intensively into politics, resulting in much discriminating legislation aimed particularly against highway transportation.

For instance, highway trucks in Texas cannot carry in excess of 7 000 lb and violations are vigorously prosecuted at the public expense to benefit the railways. In other States as much as 20 000 lb is permitted. Recently the Interstate Commerce Commission ruled an increase in billing weights on vegetables effective January 1, 1939, in Texas, New Mexico, Louisiana, and Arkansas, whereas Florida and California, the chief competitors, will not be affected. This ruling will add about $140 per car lot to an already excessive freight rate on shipments from the Rio Grande Valley, which is ruinous to the Valley growers, packers, and shippers alike. It is also proposed to repeal the long-haul and short-haul clause of the Interstate Commerce Commission Act.

Considerable statistical data have been presented by the author, and by others,[32] so that the writer has refrained from making any additions.

The enormous decline in railway business, from whatever cause, has greatly reduced income and thereby depreciated the investment securities. It has destroyed much capital value by mergers, reorganizations, and bankruptcies. What remains of a once lucrative business is now asking for Government aid, preferably in the form of an outright gift, on the plea that the other transportation agencies have enjoyed such aid not hitherto accorded the railways. This is termed the railway problem. Is this the real problem, or is it rather a case of inability to continue to attract investors in a rapidly declining business, which is over-equipped for future needs?

Originally all money invested in railway property, fixed and movable, came from the people. It was not first collected by taxation and then disbursed by the Government, after deducting a large overhead expense. Instead, the business was handled by the railway promoters themselves, and they now wish to sell the property to the Government because it is no longer profitable to operate and hold; but if the Government should buy that which was already created by the people through loss of their invested money and rates paid for service, it would mean that, ultimately, the money has come twice from the people, first to create the property and then to purchase what they have created.

---

[32] *Proceedings*, Am. Soc. C. E., November, 1938, p. 1731.

In the case of the highways and waterways the people paid only once, with the Government acting merely as a collecting and disbursing agency.

From the foregoing one must conclude that the railway problem is somewhat akin to that of any large corporate business during a period of obsolescence where the remedy, of course, would be receivership or bankruptcy. Then in the final wind-up, if the Government desired to acquire and operate the property for military or other reasons, Congress could provide the necessary legislation to create a Department of Transportation to handle all such matters, replacing the Interstate Commerce Commission, and, ultimately, to solve the railway labor question which, with other labor legislation, has become a political "foot-ball."

However, if the railways hope to rescue their property they must work out their own salvation by introducing new economies, lowering rates, catering to, and winning, the public by rendering efficient and reasonable service, and finally by recognizing the social implications of their business. The trend toward heavier locomotives and rolling stock, and adding more elaborate passenger trains, is not considered a move in the right direction because of the vastly increased maintenance cost of the road-bed. Lines that cannot exist on the available business income should be abandoned as was done with the interurban lines. Railway employees should realize that they are "killing the goose that laid the golden egg" and should accept reasonable pay reductions.

The foremost competitor of the railway is no longer the waterway but the automotive transportation on the highways. The latter, despite strenuous opposition and propaganda, burdensome traffic restrictions, license fees, and taxes, has become the choice of the people.

Were one to concede that the relations between the various transportation facilities and the City, State, and National Governments do require readjustment to rectify any inequalities supposed to exist, then the following legislative changes by Congress should receive consideration on the assumption that all fixed property be Government-owned and all transportation equipment be privately owned and operated without fees being charged:

(1) The Highways.—Repeal unfair traffic restrictions and remove license fees and gasoline taxes, the Government to build and maintain the highways, which are to be used free.

(2) The Waterways.—National improvements to be provided for navigation purposes and made free to the users.

(3) The Airways.—Remove subsidies.

(4) The Railways.—Acquire road-beds, fixed structures, such as bridges, tunnels, and stations, by purchase or, preferably, by donation. The Government would then build extensions when needed and maintain the property, the operation to be conducted by private capital as at present.

That these changes, or any of them, will ever find favor, or materialize, is highly problematical and much will depend on the funds available to each interest for propaganda purposes. The proposal to vote 6 billion dollars of credit to the railways would be a dangerous undertaking, to say the least. Although it might relieve the present financial crisis temporarily, it would not solve the railway problem. This sum of money, loaned to the railways, would only add to their present predicament; and it would further reduce the interest on their stocks, since there is no prospect of any increased earning power, and the loan would probably never be repaid.

Years ago the Canadian Government guaranteed certain outstanding obligations of its railways with the result that the properties are now practically owned by that Government. If, and when, any monetary aid is given to the railways, a safe plan would be for the Government to take a first mortgage on the property and thus be in a position to protect its own interests in case of default.

Writers on transportation problems have generally defended or favored only one system as against the others. The writer has attempted to express his unbiased opinion respecting their relations to the public.

C. A. HOGLUND,[33] ASSOC. M. AM. SOC. C. E. (by letter).—The suggestion by Mr. Lavis that a study be made of the entire transportation field in the United States is a proper one. This study should be made by men who have: (1) Knowledge of the subject by study or experience; and (2) no personal interest in the result. The entire transportation question should be approached with the thought expressed by Mr. Sheets, as quoted in the paper (see heading "The Money Question: Needed Highway Expenditures"), but with the thought that it should be applied to the entire transportation question instead of to highways. Mr. Lavis' approach to the general subject is somewhat confusing inasmuch as he discusses a special picked problem applying to each method of transportation, to the exclusion of the general problem. He also does not state the problem in such a manner that issues can be drawn as a basis of constructive discussion.

To the writer it seems that the problem should be first considered in a general manner, as for instance: At the present time what are the materials to be moved for the country as a whole? What are the methods and facilities available to move them? What consideration is being given to the relative economy and fitness of the various methods of transportation with a view to encouraging and promoting the use of each for purposes which it can serve best and most economically, while avoiding such use as is merely harmful to agencies better suited to the work?

The definite allocation of materials to be moved by a given type of transportation should be approached with caution, if at all, as the nation has not yet reached a point at which regimentation to this extent is possible. A certain theoretical recommended allocation is probably desirable only as a basis of determining theoretically whether or not there is an over-abundance of classes of transportation in a particular field, and to what extent.

Fundamentals.—Certain fundamentals should be considered before suggesting remedies or solutions for transportation generally. As a background it might be well to review the past and the present quantities to be moved and the classes of transportation.

* Reports of the Interstate Commerce Commission.

Volume of Transportation.—The volume of transportation in 1910 is unknown. The volume in 1926, 1936, and 1937 is given in Table 6.[34] The volume of traffic is less in 1936 and 1937 than in 1926, and in all probability, although the data do not show the volume in 1932, 1933, 1934, and 1935, it will probably be much less than that shown in 1926.

Changes in Ways of Transportation.—In 1910 there were approximately the following types of transportation: 240 000 miles of railroad, 200 000 miles of indifferently constructed highways, and about 30 000 miles of pipe lines—a total of approximately 470 000 miles of transportation lines. In 1930 there were 250 000 miles of railroad, 700 000 miles of fairly well co-ordinated highways (perhaps 200 000 of which were concrete or some other hard surface), 110 000 miles of oil and gasoline lines, 30 000 miles of airways, and about 10 000 miles of inland waterways—a total of not less than 1 110 000 miles of transportation lines, some of which were of almost limitless capacity or, rather, such a capacity as it now seems impossible to visualize. The foregoing shows a total increase of 136% in the total length of transportation lines in 1930 over 1910.

Over-capacity of Transportation System.—When one refers to the capacity of the transportation system, including ways, methods, and facilities of transport, it will be agreed that as a whole the system is not less than 50% more than that necessary to move the nation's production, using a prosperous year such as 1937 as the measure of an average production year. If this is true, it is axiomatic that the methods of transport should be adjusted and either reduced by law or be allowed to be reduced by competitive action without the restriction of any control.

Background of the Railroad Problem.—One of the basic questions affecting the railroads is the following: In 1910 the railroads as a whole were making money and were in practical control of the entire transportation field. There were approximately 470 000 miles of transportation lines. The railroads had no competition in the bulk transportation field of which they were not in control through relative efficiency; nor had there been any competition for about thirty years prior to this time. By better and more economical ways and methods the railroads had driven all other modes of transport from the bulk transportation field. To all intents and purposes they were a monopoly. This naturally caused the introduction of Government regulation.

---

[34] Report to the President of the United States of a Committee appointed to submit recommendations on the general transportation situation, December 23, 1938, Table 2, p. 66.

In 1930 a different situation existed, with more than 1 110 000 miles of transportation lines available. The modern highways, airways, waterways, pipe lines, and railroads now give an opportunity for one to choose other ways and methods of transport than the railroads. Highways and trucks of all sizes have opened the transport fields to every farmer and manufacturer in the United States. If a farmer does not like the freight rates, by truck or railroad, on hogs or cattle to the packing houses, he can haul by his own trucks, as illustrated by the fact that, in 1926, 90% of livestock received at 17 large markets were hauled by the railroads and 10% by motor trucks whereas, in 1937, 48% were hauled by railroads and 52% by motor trucks. If the packing houses do not believe that the rates are economical on meats by trucks or railroad, they can transport their own meats. If the steel mills or coal mines do not think the rates to the consumer are economical by the present water facilities, trucks, or railroads, they can transport by their own facilities. The ways of transportation are in existence and available for use, and their capacity has not been reached.

The methods of transport are probably as good to-day (1939) or even better than they were in 1910. Whether or not the methods of one particular class of transportation are more economical than those of another is naturally open to question. The methods and facilities on all of them are now in being and open to development regardless of existence in former times. Therefore, the railroads are in a competitive field, and Government regulation is probably not of as much service as it was in 1910 unless it is extended to cover, not only the ways, but all methods and facilities of transport. It is axiomatic, therefore, that the solution of the problem of one of the types cannot be made fairly without consideration of all classes, methods, and facilities, since they are now more or less competitive.

Increase in Railroad Capacity of Transporting Materials.—The speed of freight trains has probably doubled since 1910. As to capacity of locomotives, in 1910 the carriers had a total of 60 019 locomotives with an aggregate tractive effort of 1 588 894 000 lb and an average unit tractive effort of 27 282 lb. In 1935 they had 49 541 locomotives of which 48 477 were steam locomotives, with an aggregate tractive effort of 2 206 201 000 lb and an average tractive effort per unit of 48 367 lb.

In 1910 there were 2 148 478 freight cars with an aggregate capacity of 76 579 000 tons, or an average per unit of 35.9 tons. In 1935 there was a total of 1 867 381 units with an aggregate capacity of 88 677 000 tons, or an average per unit of 48.3 tons.

Needs of a Defense System in Times of War.—The problem of a transportation system should never be settled without giving consideration to the fact

that in time of war certain railroads, highways, waterways, pipe lines, and airways will be called upon to bear their part of the transport problem and to this extent these classes of transport are necessary to the national defense system. They should be maintained to a standard necessary to serve their objective. If the business naturally handled and the earnings obtained from this business are not sufficient to maintain them for this objective, they should be maintained with Government assistance.

***Conclusions.*—The foregoing shows that since the time when the railroads were a monopoly in the transportation field there has been an increase of 136% in the length of transportation lines generally. In addition there has been an increase in the efficiency of the railroad transportation to the extent that it would be able to handle perhaps 50% more transportation than it did in 1910, but there is a decrease in the possibilities of obtaining this traffic. The entire railroad field is burdened with over-capacity. What is shown herein relative to railroads is probably equally applicable to highways, waterways, and pipe lines. The crux of the situation—the question of over-capacity of ways, methods, and facilities of transportation—is the real problem.**

The writer has purposely omitted reference to the questions of: (1) Unjust railroad taxes; (2) inconsistencies in valuation procedure; and (3) rate of return on carriers' investment.

Item (1).—In 1933 railroads were taxed $150 000 000 less than in 1926; and in 1938, $40 000 000 less than in 1926.[35] A further review of their proportion of taxes on their investment will develop the fact that, generally, their tax burden is much less than that now being paid by the ordinary individual.

Item (2).—The value of the railroads as established by the Interstate Commerce Commission, based upon stated elements, is probably correct and proper as applied to a particular railroad. However, there is a condition of over-capacity of transportation facilities, when applied to the railroads in a freight region as a whole. The introduction of this element in the present discussion would probably reduce the values of the railroads in a freight region by not less than 30 per cent.

Item (3).—The propaganda of showing the rate of return on the carriers' investment by including the deficits of poorly paying railroads in with better paying railroads is no more proper than adding the statistics of failures among automobiles, steel, and other corporations to the good ones in obtaining their earnings as an average; and yet, nothing has been mentioned of the fact that the "dividend per cent on railroad stocks paying dividends" has never been less than 4.57% since 1891 (this low value occurred in 1932) and that the average over that period is probably not less than 6 per cent.

FRED LAVIS,[36] M. AM. SOC. C. E. (by letter).—The discussions of the paper have been very interesting and amply confirm the contention of the writer that the railway problem in the United States is one of national and very vital importance. Some of the commentators seem to have overlooked the

---

[35] Report to the President of the United States of a Committee appointed to submit recommendations on the general transportation situation, December 23, 1938, p. 78.

[36] Cons. Engr., New York, N. Y.

fact that this paper was originally presented as the opening address in the "Symposium on Transportation" offered at the Annual Convention of the Society in July of 1938, and seem to have assumed that it was a voluntary defense of the railroads rather than, as it really was, an attempt to evaluate the position of the railroads as part of the general scheme or plan of transportation in the United States.

Professor Cunningham notes that although a statement is made in the "Synopsis" that "Special stress is laid on the need for adequate research," little is said about it in the paper. This matter is referred to in more detail by Mr. Budd.

While most of the commentators agree as to the nature of the problem and its seriousness they disagree as to its solution or the remedies to be applied. Mr. Harris' indictment of present-day management, although he admits that "it is responsible for the finest system of railroads in the world," ignores a great many factors which are of vital importance to the nation in considering the problem. The greatest of these is the tyranny of railway labor and its influence on legislation. Reference was made to this in the paper but further reference may be made to a statement by Garet Garrett[37] which, while crediting the railway labor unions with a most creditable record as workmen, shows the abuses which have crept in and become established in the "constructive" rulings and in the rulings of the Railway Mediation Board.

Referring to railway and highway financing, Mr. Harris states that the main difference between them is that "The highways are not listed on the Stock Exchange." However, he ignores the fact that the Government bonds which paid for them are listed; that the capital of the banks and of the insurance companies is tied up in these bonds; that the stocks of the motor vehicle corporations are listed; and that they, with the labor organizations which are occupied in the motor vehicle industry, exercise a great deal of influence with the various State Legislatures as well as with the Congress. These factors cannot be ignored; nor can one, in facing the problems of to-day and trying to find a solution for them, get very far by blaming the financiers of yesterday.

No one realizes better than the writer the sins of railway financing in the past; but the securities issued are now in the hands of a large number of people in the United States, either directly or through the insurance policies so many of them hold. The problem is not one for the relief of Wall Street but for the relief of a very large number of the people of the United States who are not banded together and are not vocal. Above all, however, it is a problem of how to preserve a great asset of the country—one on which so many industries must depend.

Professor Cunningham points out that while it may be, or probably is, true that the railways are not over-capitalized, from the viewpoint of dollars invested, they probably are from the viewpoint of "dollars invested in facilities that are now not used or useful." Perhaps there is some little merit in this contention but it ignores the many improvements out of earnings and the more intensive use (under normal conditions) of the facilities which remain.

---

[37] "Peace on the Rails," by Garet Garrett, *The Saturday Evening Post*, September 9, 1939, p. 8.

Mr. Jenny also argues that the fact that the railroads do not earn enough to pay a fair return on their outstanding securities is evidence that they are over-capitalized. This fact, however, does not seem to be valid in view of what is said in the paper and the discussions as to the difficulties of modernizing their plant, of conducting reseach, and of being ground between the upper and lower millstones of Government regulation and labor union demands. Whether railroads are over-capitalized or not, the problem facing the nation is the rehabilitation of the transportation machine to produce ton-miles and passenger-miles efficiently and reliably at the lowest possible costs.

Perhaps the statement in the paper that Diesel engines (locomotives) have not yet progressed "much beyond the experimental stage for general railroad traction" may be subject to misinterpretation. That they are actually performing important services, with reliability, day in and day out, cannot be questioned; but in the original statement it was intended to call attention to the fact that, as yet, there is not much information at hand about final costs of service, and that Diesel engines are being used now for only a very small part of the total railway traction requirements.

Mr. Budd's remarks on the rate question, or some parts of the rate questions, are very much to the point and answer a good part of Mr. Harris' criticism of management—that is, of financial management. In times of stress, the railways are not only faced by demands for higher wages, supported by, and to all intents and purposes practically enforced by, the National Government, but are told by another Government agency what they may charge for service.

The writer is not for a moment advocating higher rates generally on railways, although some may be justified. Rather he is emphasizing that the greatest transportation agency in the United States, an agency vital to the existence of the country, is falling between the demands for higher wages, lower costs of transportation, and competition by Government financed agencies.

In the opinion of the writer, after studying the very interesting and able discussions on this subject which have appeared, it is more than ever evident that the only solution of the problem is the entire modernization of the railroad plant so that the lower costs, and therefore rates, can be produced and reasonably good wages paid. There can be little quarrel with reasonable, even something more than ordinary, compensation for railroad workers. They must have a high mental and moral standing as well as requisite skill; but many of the anomalies of "constructive" rulings should be abolished and reasonable disciplinary measures should be upheld.

No matter what form the assistance may take, the writer can see no alternative to such a subsidy to the railways as will permit this necessary modernization and the establishment of adequate research facilities on a very broad scale.

There certainly can be no more objection to this, and perhaps much more reason for it, than for the subsidies being generously donated to waterways, aviation, and highways. As for burdening the railways with debt for loans to be made, why should this be any more necessary than it has been for the construction of the other and competing facilities without placing on them any burden?

EARTHQUAKES AND STRUCTURES

BY LEANDER M. HOSKINS,[1] ESQ., AND JOHN D. GALLOWAY,[2]
M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. HOMER M. HADLEY, R. McC. BEANFIELD, R. S. CHEW, JACOB J. CRESKOFF, ARTHUR C. RUGE, WALTER L. HUBER, A. A. EREMIN, HENRY D. DEWELL, AND JOHN D. GALLOWAY AND LYDIK S. JACOBSEN.

SYNOPSIS

This paper is made up of two sections. Section I, written by Mr. Galloway, refers briefly to the work of the Earthquake Committee of the Society formed in 1923, and to its report. The nature of the earthquake waves is described and some reference is made to their cause, complexity, and characteristics. Some notes are added of the relation between earthquake waves and the structures that may be subjected to the forces arising therefrom.

Section II, by Professor Hoskins, considers the nature of the ground motion, gives certain fundamental rules and conclusions, and investigates the theory of flexure of vertical beams subjected to transverse oscillations. An extension of the theory to an elastic column sustaining a load is given in the Appendix.

I.—HISTORICAL AND DESCRIPTIVE

HISTORICAL

In 1923, after the destructive earthquake in Japan, a committee of the Society was formed with American and Japanese members. About five years were spent in assembling data, and a report was submitted to the Society. This report,[3] made up of various chapters, contained, in addition to historical and descriptive matter, a theoretical treatment of the problem of stresses in structures subject to earth movements. One paper, contributed by Professor Joseph N. LeConte, and John E. Younger, of the Uni-

versity of California, at Berkeley, Calif., was published in 1932.[4] The other paper was contributed by Professor Hoskins at the same time and revised in 1926. Section II of this paper by Professor Hoskins, contains a fundamental treatment of the problem of earthquake forces and the resulting effects upon structures subject to earthquake waves. It is a recent abridgment of the paper prepared in 1926.

THE PROBLEM

Section I describes the complex nature of the ground movements and the resulting elastic waves. The very complexity of the waves and the form and nature of various structures, such as buildings, water towers, bridge piers and trusses, etc., would seem to preclude any theoretical treatment. It would appear to be beyond the ability of any mathematician to develop formulas that would take accurate account of the extremely variable nature of the factors involved. This is true. On the other hand, the very complexity of the subject makes it necessary to approach the problem by making some general assumptions and to attempt simple solutions; for instance, it is necessary to assume a simple harmonic wave in place of the complex variable waves of the earth when in motion. It is advisable to assume a structure of uniform dimensions and material. Using these assumptions, it is possible to develop equations for moments and shear in accordance with dynamic theory. It then becomes a matter of judgment to establish a relation between any actual structure and the results of the theoretical deductions from simple assumptions that lie within the range of mathematical treatment.

It must not be inferred that more extended theoretical treatment of the problem is impossible. On the contrary, this has been done by others and with good results, especially in buildings. However, it seems desirable to present some of the fundamental conditions and treatment as a foundation for further work.

EARTHQUAKES AND THEIR EFFECTS

Any one charged with the design of engineering structures in any part of the world should take account of possible earthquake forces and the resulting stresses. Although earthquakes are generally confined to the two great belts of the earth, they may occur anywhere.

The earthquake belt that borders the Pacific Ocean passes from New Zealand, through Japan, The Islands of Alaska, California, Mexico, and the Andes, to Cape Horn. It is represented by a ring of high mountains bordering the continental shelf on the edge of the ocean depths. Japan is very close to the greatest ocean depth. There seems to be a relation between the intensity of the shocks and the nearness to great mountain chains and the ocean depths. Some minor earthquakes are volcanic, but most of them are tectonic, the result of adjustments in the crust of the earth. They are evidences of mountain building. It is thought by some that most earthquakes in California are connected with the uplift of the Sierra Nevada and the Coast mountains. The evidences are found in the numerous fault lines that traverse sections of the State. The earthquake of 1878 was caused by a slip on the Haywards fault. The earthquake of 1906 was caused by a slip on the San Andreas fault where the surface trace was evident for nearly 300 miles. The Japanese earthquake of 1923 was caused by movements in the sea bottom of Sagami Bay about 70 miles south of Yokohama, where an area of about 270 sq miles sank from 300 to 1 300 ft and an area of more than 90 sq miles was elevated from 600 to 800 ft. The earthquake of March, 1933, at Long Beach and other towns in Southern California was caused by a slip on the Inglewood fault.

---

[4] "Stresses in a Vertical Rod When Subjected to a Harmonic Motion of One End," by Joseph N. LeConte and John E. Younger, *Bulletin*, Seismological Soc. of America, Vol. 22, No. 1, March, 1932.

The rupture of the earth crust, as on the San Andreas fault (the depth of which is estimated to have been 30 miles), resulted in a maximum vertical movement of about 3 ft and a maximum differential horizontal movement of about 22 ft. It is obvious that no structure placed directly over the fault can withstand such a tearing apart of the ground. However, as a rule, the major damage is caused by the waves that travel from the disturbance.

The earth crust is not a perfect solid; it responds to the shock of rupture on the fault by a series of elastic waves that have all the characteristics of waves in a perfect medium. There are three generally recognized types of waves which move outward from the origin with different velocities, suffer reflection and interference, and probably have harmonics. The three groups have the following characteristics:

(1) Longitudinal waves that follow a curved path through the earth crust and move with a velocity of about 3.5 miles per sec;

(2) Transverse or shear waves that traverse the surface layers of the earth and move with a speed of about 2 miles per sec; and,

(3) Waves that carry the maximum amount of energy, travel through the surface, and move with a velocity of about 3 miles per sec.

In addition to these characteristics there is evidence given in almost every shock, of waves that move slowly over the surface of the ground. These waves are seen usually in alluvial soils.

The waves that damage structures are impressed waves, changing rapidly in period, amplitude, and acceleration. Seismograms rarely show traces of harmonic waves, or those with regular characteristics. This is probably a very fortunate circumstance because it prevents, to a large extent, the resonance of vibrating structures. As a result of the impressed forces generating the wave trains, the periods may vary from 0.1 sec to 2 sec, and the acceleration may vary from practically nothing to more than that of gravitation. The amplitude may vary from a small fraction of an inch to 9 in. and, possibly, to 12 in. The foundation material is the important element of the movement. Solid rock moves the least; deep alluvial soils saturated with water, such as the lands bordering the southern part of San Francisco Bay, the plain of the Los Angeles River, or the region from Tokyo to Yokohama, will have the greatest movements.

The duration of the major wave movements is an important element in the problem of the design of structures. Within limits it may be said that this time varies from a few seconds to several minutes. It will be appreciated that the duration of the destructive movements has an important bearing upon the capability of structures to withstand the earthquake. Reports indicate a duration of the sensible waves of the Long Beach earth movements as 11 sec. At Charleston, S. C., in 1886, the duration was 1 min and 10 sec; in California, in 1906, the duration was said to have been 3.5 min.

The energy released by the breaking of the earth crust is gradually dissipated during the onward progress of the waves. The destructive effects become less as the wave advances and the period of wave tends to increase to as much as 10 sec. The destructive effects are limited to a relatively small area, but the sensible shock may be felt at distances of 1 000 to 2 000 miles. Major earthquakes shake the entire globe and are detected by seismographs now installed in every civilized country.

The earth movements are very complex. All the phenomena of waves in an elastic solid are present, modified by the varying nature of the materials of the crust of the earth. One very important factor is the extreme complexity of the wave action. A movement such as that of the San Andreas fault in 1906, where the earth was ruptured for a length of 300 miles, does not generate a single wave. On the contrary, waves from innumerable foci radiate in all directions. Any given structure may be subjected to movements in all directions. It is this fact, together with the variable amplitude, period, and acceleration of the principal waves, that makes any exact mathematical treatment of structures impossible.

Relation to Structures.—It will be recognized from the foregoing brief summary of the characteristics of earthquake waves, that any structure subjected to such forces must have elements of design differing in many respects from structures subjected only to the vertical force of gravity.

One important element is the vibration period of the structure. All structures have one or more natural periods of vibration. If the period of the structure approximates closely to the periods of some of the maximum earthquake waves of the ground upon which it rests, even if such are variable, there is danger of resonance in the structure. If long continued, the cumulative effects of resonance may result in the destruction of the structure. In general, low, broad structures have vibration periods differing considerably from the periods of the maximum earthquake waves. In the case of high, narrow structures the vibration period is often close to that of some of the maximum waves and, unless the structure is well designed, serious damage will result if the shock is of long duration. The Earthquake Committee filed with its report[8] the vibration periods of a number of buildings in San Francisco, Calif., and the results would be of interest to those having such subjects under consideration. Other data of a similar kind have been published.

It is obvious that the forces generated in a structure subjected to earth movements from an earthquake are measured by the mass or weight of the building. The forces of the moving ground are unlimited. It follows from this that the use of light materials in a structure is the best and that heavy, inelastic materials should be avoided as far as possible.

The form of the structure is of importance when the design is considered. This remark applies with greatest force to buildings. A central section, with wings at right angles, suffers extensive damage, especially in the central section. The wings vibrate in different directions and with different periods, and batter the central section to its destruction.

Since the forces resulting from an earthquake are, in general, horizontal and dynamic, it follows that the design of a structure must provide for the transfer of stresses from one member to another at the connections. A reversal of stress always takes place. The structure, as a whole, is subjected to torsion and to cross-bending, from which arise tension, compression, and shearing stresses. Provision must be made in the design to resist these stresses.

Section I is presented in an attempt to explain the complex nature of the earth movements and the relation to the form of structures, the design, and the materials used. As stated, an exact treatment of the problem by mathematics is impossible, owing to the complexity of the elements of the problem. On the other hand, it is quite possible to arrive at an approximation to the stresses in a structure such as is given in Section II. If such methods are used in the light of data on possible earthquakes that are now being accumulated in all civilized countries, it will be possible to design a structure that will be consistent and thus will have every chance of passing through an earthquake without excessive damage.

II.—STRESSES AND DYNAMICAL THEORY

NATURE OF GROUND MOTION

Rules for the design of structures to resist earth shocks must be based upon definite assumptions regarding the motion of the ground. Probably the assumption most commonly made is that the motion is translational; that is, that all parts of the ground supporting the structure are at every instant moving in the same direction with a common velocity. At every instant all parts of the supporting ground will then have the same acceleration, although its value may be varying more or less rapidly in magnitude and direction.

Although it is probably true that, in many cases, the predominating motion is translational, it is not improbable that cases occur in which there is a rotational component of sufficient amplitude to be a factor in causing dangerous stresses. There is considerable testimony, in fact, to the occurrence of visible surface waves; and although such testimony often alleges wave amplitudes of incredible magnitude, it would seem that a traveling wave crest large enough to be visible must cause an appreciable rotational motion of the ground at any given spot. It will be assumed herein that the ground motion is translational unless otherwise specifically stated. In all cases, however, the solution of the dynamical problem depends upon the same fundamental principle, which it is convenient to state in the form of a general rule of procedure.

FUNDAMENTAL GENERAL RULE

The stress condition throughout the structure at any instant depends upon the accelerations of all particles of the structure at that instant. Assuming these accelerations to be known, the general rule of procedure may be stated as follows:

Assume to act upon every particle of the structure and its contents, a force equal to the product of its mass by its acceleration and opposite in direction to the acceleration. Treat the body as if in equilibrium under the action of these supposititious forces in addition to the actual forces.

The actual forces include: (*a*) Forces, such as dead weight and wind pressure, which are independent of earthquake motion; and (*b*) the supporting forces, with values that may be changed materially by the earth motion. The former are a part of the known or assumed data of the problem, whereas the latter are unknown until computed by the aid of the above rule. Just as in the ordinary problem of structural design, the supporting forces must be determined as a preliminary to the computation of the stresses. The fundamental rule is simply the application to this problem of the general principle of dynamics known as d'Alembert's principle.

APPLICATION OF GENERAL RULE ON ASSUMPTION OF RIGIDITY

If the structure is assumed to be perfectly rigid, and if it does not leave its supports, every part of it must have, at every instant, the same acceleration as the ground. The application of the general rule, therefore, is simple. Thus, if the ground has an acceleration α in a certain direction, the supposititious force assumed to act upon a particle of mass m would be a force $m\,\alpha$ opposite that direction. In other words, the magnitude of the supposititious force would be the fraction, $\frac{\alpha}{g}$, of the weight of the particle, g being the acceleration due to gravity.

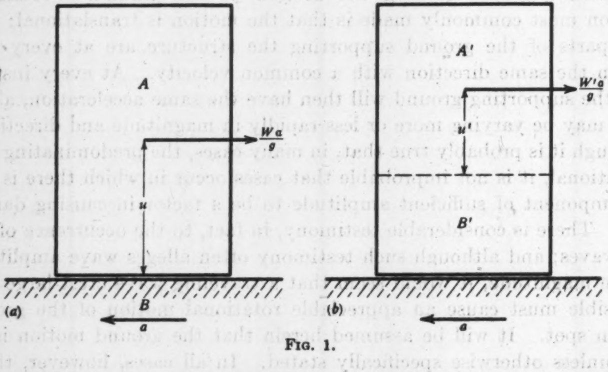

FIG. 1.

To illustrate, suppose *A* (Fig. 1(*a*)) is a rigid body supported upon the ground *B*. Let the weight of the body be *W* lb, and let *u* be the height of its mass center above the base. At a certain instant let the ground have the ac-

celeration, α, directed horizontally to the left; then the supposititious forces to be assumed to act upon the body would have a resultant of magnitude, $\frac{W\alpha}{g}$ lb, directed horizontally to the right and acting at the mass center. The supporting forces at the base must be such as to counterbalance this resultant; hence, they must be equivalent to a force, $\frac{W\alpha}{g}$ lb, directed horizontally to the left, and a couple of moment, $\frac{uW\alpha}{g}$ ft-lb, counter-clockwise. These are in addition to the supporting forces that counterbalance the weight of the body.

In like manner, if A' and B' (Fig. 1(*b*)) are the parts of the body above and below any horizontal plane, the forces exerted upon A' by B' must be such as to counterbalance the supposititious forces acting on the part, A'. If the weight of this part is W' lb, the supposititious forces have a resultant of magnitude, $\frac{W'\alpha}{g}$, directed horizontally to the right and acting at the mass center of A'; hence, the forces exerted by B' upon A' are equivalent to a force, $\frac{W'\alpha}{g}$ lb, acting horizontally to the left (shear) and a couple of moment, $\frac{u'W'\alpha}{g}$ ft-lb, counter-clockwise (resisting moment). These are additional to the forces which counterbalance the weight of A'.

If the ground has an acceleration, α, directed vertically upward, the supposititious forces are directed downward; the effect upon the supporting forces and internal stresses is the same as if the weight of every part of the structure and its contents were increased by the fraction, $\frac{\alpha}{g}$, of the actual weight. In like manner a downward acceleration of the ground would have the same effect as a decrease in the weight of the structure and its contents. Whatever the actual direction of the acceleration, its horizontal and vertical components may be treated separately. The following discussion will refer mostly to horizontal accelerations, since it is probable that, ordinarily at least, the horizontal acceleration of the ground is the principal cause of dangerous stresses. (The foregoing statements are true, of course, only when the ground motion is translational. For a rigid body, however, the computation of accelerations throughout the body due to a known rotational motion of the ground can be made without difficulty, thus determining the supposititious forces for applying the general rule.)

EFFECT OF ELASTIC YIELDING

If the acceleration of the ground varied very slowly, the departure of actual materials from perfect rigidity would have no appreciable effect upon the values of the supposititious forces referred to in the general. It would still be practically correct to assume that all parts of the structure have always the same acceleration as the ground. This is no longer true, however, if the ground is in rapid oscillation. It appears in fact that, because of elastic yielding, all parts of the structure above the foundation may have a greater range of motion than the ground, and therefore the accelerations of the upper parts may be materially greater than that of the ground. The effect of elastic yielding will depend upon the rapidity of the oscillation and upon the elastic properties, dimensions, and mass of the structure. The problem of estimating the yielding is too complex for exact mathematical treatment unless simplified by assumptions which are far from true in the case of many structures. It is possible, however, to infer something regarding the nature of the effects to be expected, from well-known considerations relating to oscillating systems in general. It seems possible, also, to throw some light on the possible order of magnitude of these effects by solving the dynamical problem for idealized simple cases.

CONCLUSIONS FROM GENERAL THEORY OF FORCED AND FREE OSCILLATIONS

The problem under consideration falls under the general case of a system which is constrained to oscillate with a certain definite frequency. (By frequency is meant the number of complete oscillations per unit time. Frequency is the reciprocal of period.) General theory indicates that the phase and amplitude of the forced oscillation will depend upon the relation between its frequency and that of the "natural" or "free" oscillation which the system might have. For the simple case of a system having only one degree of freedom and, therefore, one possible mode of vibration, the following statements hold:

(*a*) *Phase of Forced Oscillation.*—If the disturbing oscillation has a less frequency (that is, a longer period) than the free oscillation, the system will oscillate in the same phase as the disturbance that causes it. If the disturbance has a frequency greater than that of the free oscillation, the phase of the actual oscillation will be opposite to that of the disturbance.

(*b*) *Amplitude of Forced Oscillation.*—The amplitude of the forced oscillation is greater the more nearly its frequency approaches that of the free oscillation; that is, if f_0 is the frequency of the free oscillation and f that of the disturbance, the amplitude of the forced oscillation will be greater the nearer $\frac{f}{f_0}$ is to 1. Moreover, as $\frac{f}{f_0}$ approaches 1 the amplitude increases without limit.

These statements refer to undamped oscillations. In the case of an oscillating building the damping (due to internal friction and to air resistance) is presumably too small to affect the validity of the propositions stated. It should further be noted that a system having more than one degree of freedom may have more than one possible mode of free oscillation; for elastic structures the number of possible modes may, in fact, be indefinitely great. In applying Statements (*a*) and (*b*) to such a case it is to be understood that the mode referred to is generally that of longest period, which may be regarded as the fundamental mode.

These statements indicate, at least in a general way, the nature of effects that might be caused in an elastic structure by a simple harmonic oscillation of the supporting ground. Proposition (*b*) is of especial importance, since it indicates that if a structure has a natural oscillation period that is nearly the same as that of the ground motion, continued repetition of the earth tremors will inevitably result in dangerous stresses. Whether this condition is actually of frequent occurrence, and whether it is possible to guard against it by proper design, would seem to be questions of fundamental importance. To answer the former question with certainty it would be necessary to have full knowledge regarding the frequencies of the harmonic components of ground oscillations occurring in violent earthquakes, and also regarding free-oscillation frequencies of actual buildings. It can scarcely be doubted, however, that observed destructive effects have in some cases been due to the cause stated.

As regards the second question, it is obvious that the designer is powerless to avoid the dangerous condition unless he is able to estimate in advance the natural oscillation frequency of any projected building. Of great value for this purpose would be data concerning actual oscillation periods of many existing structures so selected as to serve as types. The problem of the structural designer in the matter of avoiding dangerous oscillations thus depends very largely upon data which can be obtained only by observation of actual structures and actual earthquakes. It remains to consider whether further light can be thrown upon the problem by dynamical theory.

As already stated, the possibility of exact mathematical treatment depends upon the introduction of assumptions which are often far from representing the facts for actual structures. The solution of such idealized problems, however, may be of use as indicating the general character and order of magnitude of the effects likely to be caused by elastic oscillation. One such problem will now be considered.

OSCILLATION OF A UNIFORM VERTICAL BEAM

The ideal problem treated in the following analysis is that of a uniform beam placed in a vertical position with the upper end free and the lower end rigidly attached to the ground, the supporting ground being assumed to have a horizontal motion resolvable into components which are simple harmonic functions of the time. The method of solution consists in forming the differential equation of the elastic curve by a simple extension of the ordinary theory of flexure, and solving this equation subject to the conditions assumed to hold at the ends. From the equation of the elastic curve, it is easy to deduce formulas for the shear and resisting moment at any cross-section of the oscillating beam. The solution given herein was formulated by the writer in 1926 when the original draft of this paper was prepared for the Special Committee on Effects of Earthquakes on Engineering Structures (not published). The same fundamental theory has been employed by many writers both before and since that date. A partial list of publications is given at the end of this paper.

THEORY OF FLEXURE APPLIED TO OSCILLATING BEAM

The following deduction of the differential equation of the elastic curve is applicable to the general case of a uniform elastic beam performing small transverse oscillations. The notation introduced, however, is especially adapted to the foregoing problem. The quantities involved are the following: h = length of beam; A = its cross-sectional area; $I = A\,k^2$ = moment of inertia of cross-section about axis of bending; W = total weight of beam, in pounds; E = modulus of elasticity of material (Young's modulus); g = acceleration due to gravity; and, M and V = resisting moment and resisting shear acting at any transverse section.

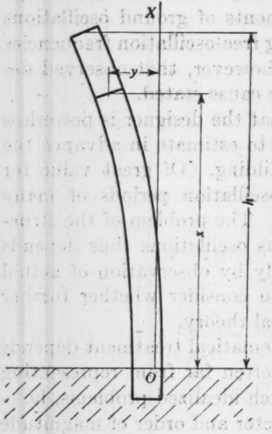

FIG. 2.

Let x, y denote the rectangular co-ordinates of any point in the elastic curve with respect to axes taken as in Fig. 2. The origin, O, is taken at the base of the beam in its mean position, the positive X-direction is vertically upward, and the positive Y-direction is horizontally to the left. The convention of signs for M and V is as follows: The part of the beam above the cross-section exerts upon the part below, forces of which V is the sum of the components in the positive Y-direction and M is the sum of the moments in the counter-clockwise sense.

The first step is to write the dynamical equations for an element of the beam bounded by two transverse sections at x and $x + dx$. The acceleration of this element in the X-direction is inappreciable while its Y-acceleration is $\frac{\partial^2 y}{\partial t^2}\cdot$ Its angular acceleration is $\frac{\partial^2 \phi}{\partial t^2}$ in which ϕ differs inappreciably from $\frac{\partial y}{\partial x}$. The mass of the element is $\frac{W\,dx}{g\,h}$ and its moment of inertia about the axis of bending is $\left(\frac{W\,dx}{g\,h}\right)k^2$. The total force acting on the element in the Y-direction is $\left(\frac{\partial V}{\partial x}\right)dx$; the total turning moment acting on it is $\left(\frac{\partial M}{\partial X}\right)dx + V\,dx$. Hence, the equations of linear and angular motion for the element may be written as follows (after cancellation of dx):

$$\frac{W}{g\,h}\frac{\partial^2 y}{\partial t^2} = \frac{\partial V}{\partial x} \qquad \text{(1)}$$

and

$$\frac{W\,k^2}{g\,h}\frac{\partial^2}{\partial t^2}\left(\frac{\partial y}{\partial x}\right) = \frac{\partial M}{\partial x} + V \qquad \text{(2)}$$

Eliminating V between Equations (1) and (2), there results,

$$\frac{W\,k^2}{g\,h}\frac{\partial^4 y}{\partial t^2\,\partial x^2} - \frac{W}{g\,h}\frac{\partial^2 y}{\partial t^2} = \frac{\partial^2 M}{\partial x^2} \qquad \text{(3)}$$

As in the ordinary theory of flexure,

$$M = E\,I\frac{\partial^2 y}{\partial x^2} \qquad \text{(4)}$$

so that Equation (3) reduces to the form,

$$\frac{\partial^2 y}{\partial t^2} + \frac{E\,I\,h\,g}{W}\frac{\partial^4 y}{\partial x^4} - k^2 \frac{\partial^4 y}{\partial t^2\,\partial x^2} = 0 \qquad (5)$$

It is found that the third term in Equation (5) is practically negligible unless the beam is short in comparison with its transverse dimensions, and in the following solution this term is omitted. (If the third term is retained the solution is entirely practicable, but involves considerably more labor, especially in numerical applications.) It is to be noted that the omission of this term reduces Equation (2) to the form,

$$V = -\frac{\partial M}{\partial x} \qquad (6)$$

as in the theory of beams under static conditions.

SOLUTION OF THE DIFFERENTIAL EQUATION WHEN THE GROUND MOTION IS A SIMPLE HARMONIC OSCILLATION

If the ground motion is resolved into components, each of which is a simple harmonic oscillation, each component may be treated separately. It suffices, therefore, to consider the solution of the differential equation,

$$\frac{\partial^2 y}{\partial t^2} + \frac{E\,I\,h\,g}{W}\frac{\partial^4 y}{\partial x^4} = 0 \qquad (7)$$

on the assumption that the lower end of the beam is constrained to have a simple harmonic oscillation in a horizontal plane. This gives one of four boundary conditions; the other three being that $\frac{\partial y}{\partial x}$ is always zero at the lower end, and that M and V are always zero at the upper end. Noting the general values of M and V as given by Equations (4) and (6), the boundary conditions may be stated as follows:

When $x = 0$,

$$y = a \sin\left(\frac{2\,\pi\,t}{T} + q\right) \qquad (8a)$$

when $x = 0$,

$$\frac{\partial y}{\partial x} = 0 \qquad (8b)$$

when $x = h$,

$$\frac{\partial^2 y}{\partial x^2} = 0 \qquad (8c)$$

and when $x = h$,

$$\frac{\partial^3 y}{\partial x^3} = 0 \qquad (8d)$$

The amplitude and period of the forced oscillation are here represented by a and T, and q is a constant the value of which depends upon the choice of the origin of time.

It is easily verified that the differential equation and the four boundary conditions may be satisfied by assuming:

$$y = (A_1 \cos m\, x + B_1 \sin m\, x + A_2 \cosh m\, x + B_2 \sinh m\, x)$$
$$\times \sin\left(\frac{2\,\pi\, t}{T} + q\right) \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

and assigning proper values to the constants m, A_1, B_1, A_2 and B_2. Thus, the differential equation is satisfied if,

$$m^4 = \frac{4\,\pi^2\,W}{E\,I\,h\,g\,T^2} \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

and the boundary conditions give the four equations,

$$A_1 + A_2 = a \ldots\ldots\ldots\ldots\ldots\ldots (11a)$$

$$B_1 + B_2 = 0 \ldots\ldots\ldots\ldots\ldots\ldots (11b)$$

$$-A_1 \cos m\, h - B_1 \sin m\, h + A_2 \cosh m\, h + B_2 \sinh m\, h = 0 \ldots (11c)$$

$$A_1 \sin m\, h - B_1 \cos m\, h + A_2 \sinh m\, h + B_2 \cosh m\, h = 0 \ldots (11d)$$

which determine A_1, B_1, A_2, B_2, when m is known, their values being as follows:

$$A_1 = \frac{a}{2}\left(1 - \frac{\sin m\, h \sinh m\, h}{1 + \cos m\, h \cosh m\, h}\right) \ldots\ldots\ldots\ldots (12a)$$

$$B_1 = \frac{a}{2}\left(\frac{\cos m\, h \sinh m\, h + \sin m\, h \cosh m\, h}{1 + \cos m\, h \cosh m\, h}\right) \ldots (12b)$$

$$A_2 = a - A_1 \ldots\ldots\ldots\ldots\ldots\ldots (12c)$$

and,

$$B_2 = -B_1 \ldots\ldots\ldots\ldots\ldots\ldots (12d)$$

Formulas for M and V are easily written from Equations (4) and (6).

CASE OF FREE OSCILLATION

If the ground is at rest the foregoing solution is still valid with $a = 0$. In this case Equations (11) determine only the ratios of the four constants A_1, B_1, A_2, and B_2, their actual values containing a factor with an arbitrary value. Moreover, in this case the equations can be satisfied only by restricting T to certain values. For by eliminating A_1, B_1, A_2, and B_2 from Equations (11) there results the equation,

$$1 + \cos m\, h \cosh m\, h = 0 \ldots\ldots\ldots\ldots\ldots\ldots (13)$$

which must be satisfied by any permissible value of m, while T depends upon m according to Equation (10).

Equation (13) is satisfied by each of an infinite series of values of mh, which may be determined by trial to any desired degree of approximation. In order of magnitude the first three values are 1.8751, 4.6944, and 7.8548; the succeeding values differ very slightly from $\frac{7\pi}{2}$, $\frac{9\pi}{2}$, etc. Each of these values corresponds to a possible free oscillation, the period of which may be computed by Equation (10). The greatest of the possible free periods may be called the fundamental period, a formula for which may be obtained by taking $m = m_0 = \frac{1.8751}{h}$. Calling this period, and the corresponding frequency, T_0 and f_0, and using Equation (10),

$$T_0 = \frac{1}{f_0} = \frac{2\pi}{m_0^2}\sqrt{\frac{W}{E\,I\,h\,g}} = \frac{2\pi}{(1.8751)^2}\sqrt{\frac{W\,h^3}{E\,I\,g}} = 1.787\sqrt{\frac{W\,h^3}{E\,I\,g}} \;\ldots (14)$$

It may easily be verified that the successive free oscillations have periods the ratios of which to T_0 are: 1, 0.1595, 0.05699, 0.02908, 0.01759, etc. These numbers, beginning with the fourth, are to a close approximation proportional inversely to the squares of the odd numbers 7, 9, 11, etc.

FORCED OSCILLATION OF ASSIGNED PERIOD

It is seen that, for a given beam, the assignment of values to a and T determines all the constants, m, A_1, B_1, A_2, and B_2, so that (except in the case of free oscillation) the values of y, M, and V, at all sections, may be computed by Equations (9), (4), and (16). In examining the nature of the results for various particular cases it is convenient to take as a basis of comparison the ideal case of no elastic yielding.

Case of Perfect Rigidity.—For this case let the values of y, M, and V, for any value of x, be y', M', and V', and let values for $x = 0$ be y_0', M_0', and V_0'. Denoting the ground acceleration by α and reasoning as before (see heading "Application of General Rule on Assumption of Rigidity") there result the formulas:

$$M_0' = -\frac{W\,h}{2\,g}\alpha \;\ldots\ldots (15a)$$

$$V_0' = -\frac{W}{g}\alpha \;\ldots\ldots (15b)$$

$$M' = M_0'\left(1 - \frac{x}{h}\right)^2 \;\ldots\ldots (15c)$$

$$V' = V_0'\left(1 - \frac{x}{h}\right) \;\ldots\ldots (15d)$$

Since the motion of the ground is assumed to be represented by the formula,

$$y_0' = a \sin\left(\frac{2\pi t}{T} + q\right) \;\ldots\ldots (16)$$

the acceleration is,

$$\alpha = \frac{\partial^2 y_0'}{\partial t^2} = -\frac{4\pi^2}{T^2} a \sin\left(\frac{2\pi t}{T} + q\right) \;\ldots\ldots (17)$$

Effect of Elastic Yielding.—Equations (4), (6), (9), (10), and (15) lead easily to the following formulas:

$$\frac{y}{y_0'} = \frac{A_1}{a} \cos m\,x + \frac{B_1}{a} \sin m\,x + \frac{A_2}{a} \cosh m\,x + \frac{B_2}{a} \sinh m\,x \ldots (18a)$$

$$\frac{M}{M_0'} = \frac{2}{m^2\,h^2}\left(- \frac{A_1}{a} \cos m\,x - \frac{B_1}{a} \sin m\,x + \frac{A_2}{a} \cosh m\,x + \frac{B_2}{a} \sinh m\,x \right) \ldots (18b)$$

$$\frac{V}{V_0'} = \frac{1}{m\,h}\left(- \frac{A_1}{a} \sin m\,x + \frac{B_1}{a} \cos m\,x - \frac{A_2}{a} \sinh m\,x - \frac{B_2}{a} \cosh m\,x \right) \ldots (18c)$$

Equations (18*b*) and (18*c*), compared with Equations (15*c*) and (15*d*), show the effect of elastic yielding upon the values of the bending moment and shear at any section of the beam. It is seen that, for a given value of $\frac{x}{h}$, the values of $\frac{M}{M_0'}$ and $\frac{V}{V_0'}$ depend solely upon the value of $m\,h$. Moreover, $m\,h$ depends only upon the value of $\frac{T_0}{T}$, since by Equation (10),

$$\frac{m^2\,h^2}{m_0^2\,h^2} = \frac{T_0}{T} \ldots (19)$$

while $m_0\,h$ has the fixed value 1.8751, so that,

$$m\,h = 1.8751 \sqrt{\frac{T_0}{T}} \ldots (20a)$$

$$m\,x = 1.8751 \sqrt{\frac{T_0}{T}}\,\frac{x}{h} \ldots (20b)$$

Thus, if K is written for $1.8751 \sqrt{\frac{T_0}{T}}$, x' for $\frac{x}{h}$, and A_1', B_1', A_2', and B_2' for $\frac{A_1}{a}$, $\frac{B_1}{a}$, $\frac{A_2}{a}$, and $\frac{B_2}{a}$, Equations (18) become:

$$\frac{y}{y_0'} = A_1' \cos K\,x' + B_1' \sin K\,x' + A_2' \cosh K\,x' + B_2' \sinh K\,x' \ldots (21a)$$

$$\frac{M}{M_0'} = \frac{2}{K^2}\left(- A_1' \cos K\,x' - B_1' \sin K\,x' + A_2' \cosh K\,x' + B_2' \sinh K\,x'\right) \ldots (21b)$$

and,

$$\frac{V}{V_0'} = \frac{1}{K}\left(- A_1' \sin K\,x' + B_1' \cos K\,x' - A_2' \sinh K\,x' - B_2' \cosh K\,x'\right) \ldots (21c)$$

in which (from Equations (12)):

$$A_1' = 1 - A_2' = \frac{1}{2}\left(1 - \frac{\sin K \sinh K}{1 + \cos K \cosh K} \right) \ldots (22a)$$

$$B_1' = - B_2' = \frac{1}{2}\left(\frac{\cos K \sinh K + \sin K \cosh K}{1 + \cos K \cosh K} \right) \ldots (22b)$$

All the constants in the formulas thus depend upon the single number K, which itself depends upon $\frac{T_0}{T}$. In other words, for a given value of $\frac{x}{h}$, the ratio of change in M and in V, due to elastic yielding, depends solely upon the ratio of the actual oscillation period to the fundamental free period, being wholly independent of the dimensions and material of the beam, except as these factors determine the value of T_0.

Characteristic Curves.—The graphs of Equations (21) may be called characteristic curves for the problem under consideration. Such curves are shown in Fig. 3. Each curve is marked with the appropriate value of $\frac{T_0}{T}$, the range of such values being from 0 (perfect rigidity) to 0.9 and from 1.1 to 1.5. The curves illustrate in a striking manner the rôle played by the free period T_0. The foregoing statements (see heading "Conclusions from General Theory of Forced and Free Oscillations"), regarding phase and amplitude of forced oscillations in general are clearly illustrated in Fig. 3(a), and Figs. 3(b) and 3(c) show the rapid increase of M and V as the case $T = T_0$ is approached.

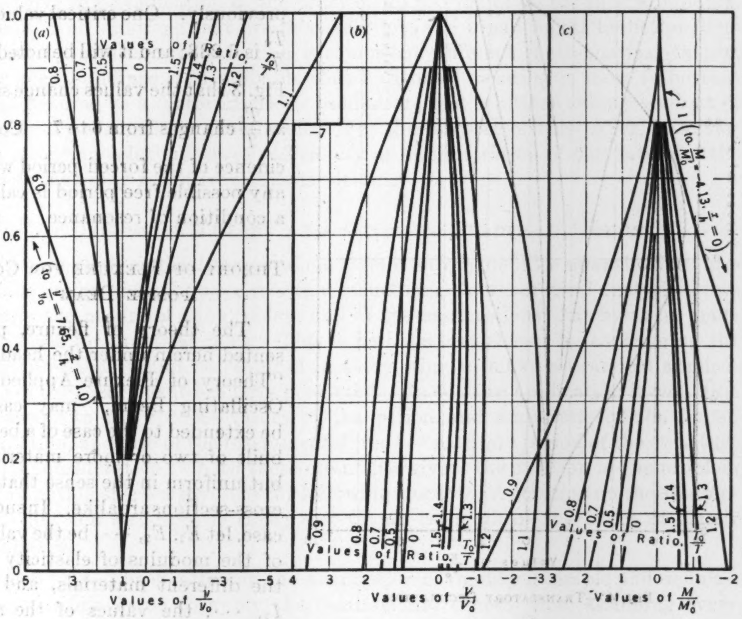

FIG. 3.

Curves for $\frac{y}{y_0}$, covering a greater range of values of $\frac{T_0}{T}$ are shown in Fig. 4. These curves are of especial interest as showing the transition from the first to the second of the natural periods. In the case of perfect rigidity, $\frac{T_0}{T} = 0$, so that the ratio of change in M and V, due to elastic yielding, is found by comparing each value computed by Equations (21) with the corresponding value computed from Equations (15). Infinite values of y, M, and V result if T is equal to T_0, or to any one of the possible free periods specified previously. One critical value of $\frac{T_0}{T}$ is 6.238; and it will be noted in Fig. 3 that the values change sign as $\frac{T_0}{T}$ changes from 6 to 7. Coincidence of the forced period with any possible free period is called a condition of resonance.

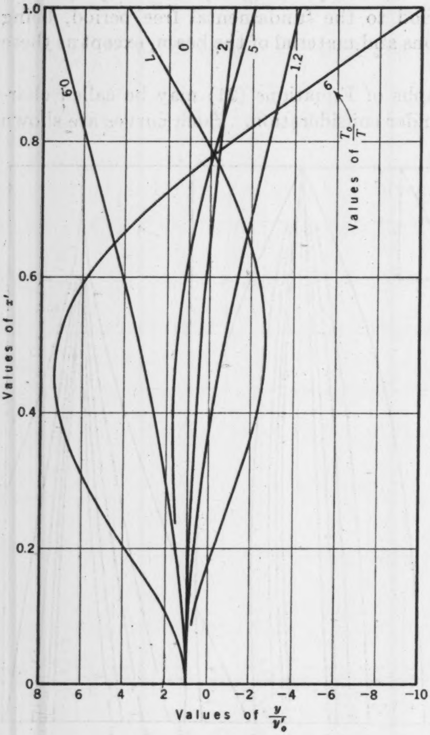

FIG. 4.—TRANSLATORY OSCILLATION.

THEORY OF FLEXURE FOR COMPOSITE BEAM

The theory of flexure, presented herein under the heading "Theory of Flexure Applied to Oscillating Beam," may easily be extended to the case of a beam built of two or more materials, but uniform in the sense that all cross-sections are alike. In such a case, let $E_1, E_2, \cdots$, be the values of the modulus of elasticity for the different materials, and $I_1, I_2, \cdots$, the values of the moment of inertia for the corresponding parts of the cross-section; then, the formula for the resisting moment is:

$$M = (E_1 I_1 + E_2 I_2 + \cdots) \frac{\partial^2 y}{\partial x^2} \quad \ldots\ldots\ldots\ldots\ldots (23)$$

The use of Equation (23) instead of Equation (4) introduces no change in the differential Equation (7), except that EI must be replaced by $E_1 I_1 + E_2 I_2 + \cdots$. With this change the case of a composite beam is covered by the solution given above. It is of especial interest to note the application of this statement to the formula for T_0 (Equation (14)). (In the interest of rigor it should be noted that the radius of gyration, k, occurring in Equations (2) and (5) applies not simply to the area of the cross-section, but to the mass of an elementary layer. In the foregoing solution, however, terms involving k have been treated as negligible.)

ACTUAL AND IDEAL STRUCTURES

It cannot be supposed that numerical results computed for the foregoing ideal problem apply closely to actual buildings, but the general character of the results probably represents the kind of effects to be expected in a steel frame building which is uniform in horizontal area and tall in comparison with its horizontal dimensions. It would seem, for example, that Equation (14) may give some indication of the order of magnitude of T_0 for such a building. The case of buildings that are relatively low and broad might be better illustrated by solutions based upon a somewhat different mathematical theory. For such buildings it is probable that horizontal shearing is more important than bending as a factor in elastic oscillation, and solutions taking account of this factor are entirely practicable. For the purpose of this paper, however, the foregoing solution serves sufficiently as an illustration of the nature of the effects that may result from elastic yielding.

DYNAMICAL THEORY AS A GUIDE TO PRACTICAL DESIGN

Although dynamical theory alone cannot supply definite quantitative rules for the design of earthquake-resistant structures, the theoretical analysis shows clearly the nature of the problem and of the assumptions that must be made as a basis for practical rules. This is perhaps best shown by considering the procedure that would be required in attempting to make a practical application of the theory as it has been presented. In such an application it would be necessary to use specific values of the period and amplitude of the forced oscillation, and also of the fundamental free or "natural" period of the structure under consideration. With these quantities given, the solution of the problem of computing stresses involves the following steps: (*a*) A solution on the assumption that the structure is rigid; and (*b*) an estimate of the effect of elastic oscillation:

Step (*a*).—The solution on the assumption of rigidity is simple and definite, the procedure being to apply the fundamental general rule, assuming every part of the building and its contents to have the same acceleration as the ground. The computation of the supporting forces and of the stresses in the framework is then an ordinary problem in structural mechanics.

Step (*b*).—To determine, quantitatively, the ratio of change of the stresses due to elastic oscillation would require a solution of the elastic problem for the actual structure similar to that which has been given for the ideal structure treated as a uniform beam. In the ideal problem it was found that elastic yielding increased the values of V and M by ratios depending upon the value of $\frac{T_0}{T}$, the effects being shown quantitatively in Figs. 3(*b*) and 3(*c*). Although these quantitative results cannot be assumed to hold for the actual problem, it is reasonable to assume that certain important characteristics of the results do hold; namely (1) that the values of V and M are increased by elastic yielding and (2) that the ratio of change in V and in M depends upon the ratio $\frac{T_0}{T}$ and increases without limit as T approaches equality with T_0, or with any other of the natural periods of the structure.

Dynamical theory thus makes clear the nature of earthquake hazards, and at the same time shows the difficulty of formulating practical rules for meeting the hazards because of uncertainty regarding the actual data that should be assumed to apply to any particular case. There is one fundamental practical rule, however, which may be stated with confidence:

Fundamental Practical Rule.—The structure should be designed to resist forces, $m\,\alpha$, acting on all its particles in any horizontal direction, α being the probable maximum ground acceleration and m the mass of any particle.

The value of α to be used in applying this rule is a matter for the judgment of the engineer, guided by records of actual earthquakes. Different authorities have recommended values from 2% to 10% of gravity.

Danger of Resonance.—It is clear that very great stresses may result if there is a near approach to a condition of resonance; that is, equality of T to one of the natural periods of the structure. Since any given structure has a multiplicity of natural periods, and since the harmonic analysis of seismograph records has shown a considerable range of values of T, it seems impracticable to formulate any simple rule for minimizing the probability of dangerous stresses due to resonance.

PUBLICATIONS DEALING WITH THE VIBRATION OF PRISMATIC BARS

The theory of the elastic vibration of prismatic bars has been discussed by many writers during the past 200 yr, among the earliest having been Daniel Bernoulli (about 1743) and his contemporary, Bernhard Euler. The deduction of the differential equation of the elastic curve, in the form given in this paper when gravity is neglected, and its solution subject to stated boundary conditions, are found in numerous publications, of which a few are listed subsequently. Of these, Nos. (5) and (6) treat the same case of the oscillating vertical beam as that treated in this paper, with substantially identical results.

APPENDIX

EXTENSION OF THEORY DESIRABLE

The theory of the uniform vertical beam or column has served to illustrate the general character of effects which may be caused in structures of a certain type by a forced harmonic oscillation. It seems desirable to extend the theory so as to cover a more general class of cases than has been treated previously. In this more general treatment special attention will be given to the important case of free oscillation.

ELASTIC COLUMN SUSTAINING A LOAD

Let the vertical beam or column treated in Fig. 2 be assumed to carry at its upper end a rigid body weighing P lb. Let the mass center of this body lie in the extension of the axial line of the column at a distance h' from the top; let k' be the radius of gyration of its mass with respect to an axis through its mass center perpendicular to the plane of flexure of the column; and let other data and notation be as in the problem already solved. This case is represented diagrammatically in Fig. 5(a).

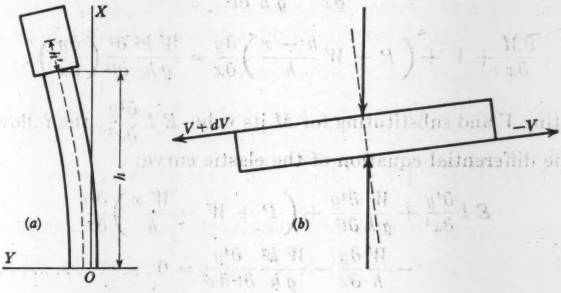

FIG. 5.

DIFFERENTIAL EQUATION OF ELASTIC CURVE

In the theory already given the action of gravity on the column was neglected. The following is a more rigorous analysis, taking account of the weight of the column itself as well as that of the supported load. In order to form the differential equation of the elastic curve, write the equations of linear and angular acceleration of an element of the column of thickness dx, bounded by transverse planes normal to the curve. (It will be assumed as before that horizontal shearing is negligible in comparison with bending in determining the form of the elastic curve.) Such an element is represented in Fig. 5(b).

The mass of the element is $\frac{W\,dx}{g\,h}$, and its moment of inertia about its central axis is $\left(\frac{W\,dx}{g\,h}\right)k^2$. Its acceleration in the X-direction is inappreciable, and its

Y-acceleration is $\frac{\partial^2 y}{\partial t^2}$. Its angular acceleration is $\frac{\partial^2 \phi}{\partial t^2}$, in which ϕ differs inappreciably from $\frac{\partial y}{\partial x}$.

The forces acting on the element are as follows: Forces $-V$ and $+(V + dV)$ acting in practically horizontal directions on the lower and upper faces; couples of moments $-M$ and $+(M + dM)$, acting on the same faces; a vertical force, $P + W\frac{h - x}{h}$, acting upward on the lower face, and a vertically downward force, less by $\left(\frac{W\,dx}{h}\right)$, acting on the upper face. Each of these vertical forces, being uniformly distributed over the cross-section, may be regarded as applied at the centroid, the distance between their lines of action being dy. (The reasoning here is that of the common theory of flexure, which assumes that the normal stresses on a cross-section are equivalent to a normal force applied at the centroid, together with a couple of which the moment is the resisting moment M.) The equations of linear and angular motion for the element, therefore, may be written as follows (after dividing by dx):

$$\frac{\partial V}{\partial x} = \frac{W}{g\,h}\frac{\partial^2 y}{\partial t^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (24a)$$

and,

$$\frac{\partial M}{\partial x} + V + \left(P + W\frac{h - x}{h}\right)\frac{\partial y}{\partial x} = \frac{W\,k^2}{g\,h}\frac{\partial^2}{\partial t^2}\left(\frac{\partial y}{\partial x}\right) \quad \ldots\ldots (24b)$$

Eliminating V and substituting for M its value $E\,I\,\frac{\partial^2 y}{\partial x^2}$, the following is obtained as the differential equation of the elastic curve:

$$E\,I\,\frac{\partial^4 y}{\partial x^4} + \frac{W}{g\,h}\frac{\partial^2 y}{\partial t^2} + \left(P + W - \frac{W\,x}{h}\right)\frac{\partial^2 y}{\partial x^2}$$
$$- \frac{W}{h}\frac{\partial y}{\partial x} - \frac{W\,k^2}{g\,h}\frac{\partial^4 y}{\partial t^2 \partial x^2} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (25)$$

Comparing Equation (25) with Equation (5), it is seen that the latter consists of the first, second, and last of the terms in the former, while in Equation (7), which was actually solved, only the first two terms are retained. Next, consider whether a more rigorous treatment which retains some or all of the omitted terms is practicable or desirable. For this purpose, note the meanings of the different terms as well as their relative magnitudes.

Any given element of mass influences the oscillation of the system in two ways—by its inertia and by its weight. The latter effect was wholly disregarded in the theory leading to Equation (5). In the problem there treated (in which the only mass present was that of the column itself) the effect of gravity is represented in Equation (25) by the terms: $\left(W - \frac{W\,x}{h}\right)\frac{\partial^2 y}{\partial x^2} - \frac{W}{h}\frac{\partial y}{\partial x}$. When these terms are retained, and when $P = 0$, Equation (25) can be solved by development in series, and it is not difficult to prove that the effect of gravity is of slight importance in that problem. In the more general case now under consideration there is the additional gravity effect due to the load P, and it seems probable that there may be cases in which this effect will be of much greater importance than that of the weight of the column itself. In the analysis which follows, therefore, the term containing P is retained but those terms representing the effect of gravity on the column itself are omitted.

The inertia effect is represented in Equation (25) by the second and last terms, of which the former represents the linear inertia of the mass element and the latter its angular inertia. Of these terms the latter is ordinarily of negligible importance and will not be retained. The inertia effect of the load P does not affect the differential Equation (25), but is included in the boundary conditions to be given subsequently.

With the approximations stated the differential equation to be solved reduces to the following:

$$E\,I\frac{\partial^4 y}{\partial x^4} + \frac{W}{g\,h}\frac{\partial^2 y}{\partial t^2} + P\frac{\partial^2 y}{\partial x^2} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

It remains to formulate the boundary conditions.

The ground motion and the method of supporting the column being the same as in the problem already solved, the boundary conditions at $x = 0$ are expressed by Equations (8a) and (8b). In the present case, however, it cannot be assumed that V and M are zero at $x = h$; instead it is necessary to write the equations of linear and angular motion for the body P. Let the values of V, M, y, and $\frac{\partial y}{\partial x}$ at the top of the column be V_1, M_1, y_1, and ϕ_1. If the body is rigid and rigidly attached to the top of the column, the value of y for its mass center is $y_1 + h'\,\phi_1$. Therefore, for the body P:

The acceleration of the mass center is $\frac{\partial^2 y_1}{\partial t^2} + h'\left(\frac{\partial^2 \phi_1}{\partial t^2}\right)$, the force causing this acceleration is $-V_1$; the angular acceleration is $\frac{\partial^2 \phi_1}{\partial t^2}$, and the torque about the mass center is $-M_1 + V_1\,h' + P\,h'\,\phi_1$, from which follow the two equations:

$$\frac{P}{g}\left(\frac{\partial^2 y_1}{\partial t^2} + h'\frac{\partial^2 \phi_1}{\partial t^2}\right) = -V_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots (27a)$$

$$\frac{P\,(k')^2}{g}\frac{\partial^2 \phi_1}{\partial t^2} = -M_1 + V_1\,h' + P\,h'\,\phi_1 \quad \ldots\ldots\ldots\ldots (27b)$$

The values of V_1 and M_1 to be substituted in Equations (27) are obtained from the general formulas:

$$M = E\,I\frac{\partial^2 y}{\partial x^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (28a)$$

$$V = -\frac{\partial M}{\partial x} - P\frac{\partial y}{\partial x} \quad \ldots\ldots\ldots\ldots\ldots\ldots (28b)$$

the latter being equivalent to Equation (24b) when the terms containing W are treated as negligible. The four boundary conditions may now be written

as follows:

When $x = 0$,

$$y = a \sin\left(\frac{2\pi t}{T} + q\right) \quad \text{(29a)}$$

when $x = 0$,

$$\frac{\partial y}{\partial x} = 0 \quad \text{(29b)}$$

when $x = h$,

$$\frac{P}{g}\left(\frac{\partial^2 y}{\partial t^2} + h'\frac{\partial^2}{\partial t^2}\left(\frac{\partial y}{\partial x}\right)\right) = E\,I\,\frac{\partial^3 y}{\partial x^3} + P\frac{\partial y}{\partial x} \quad \text{(29c)}$$

and when $x = h$,

$$P\,\frac{(k')^2}{g}\,\frac{\partial^2}{\partial t^2}\left(\frac{\partial y}{\partial x}\right) = -\,E\,I\left(\frac{\partial^2 y}{\partial x^2} + h'\,\frac{\partial^3 y}{\partial x^3}\right) \quad \text{(29d)}$$

The general problem thus reduces to the solution of the differential Equation (26) subject to the boundary conditions, Equations (29). It must be remembered that, in the problem as thus formulated, the column is regarded as having inertia, but not weight; for the supported body, however, the equations take account of both inertia and weight. It is proposed first to outline the solution of this problem in its generality, and then to consider solutions based upon certain simplifying assumptions which, in some cases, may be permissible.

GENERAL SOLUTION

For conciseness the following notation will be used:

$$\theta = h\sqrt{\frac{P}{E\,I}} \quad \text{(30a)}$$

$$\theta' = h\sqrt{\frac{W}{E\,I}} \quad \text{(30b)}$$

and,

$$u^2 = \frac{g\,T^2}{(4\,\pi^2\,h)} \quad \text{(30c)}$$

Equation (26) may be written:

$$\frac{\partial^4 y}{\partial x^4} + \frac{\theta^2}{h^2}\frac{\partial^2 y}{\partial x^2} + \frac{\theta'^2}{g\,h^3}\frac{\partial^2 y}{\partial t^2} = 0 \quad \text{(31)}$$

It is found that a solution of Equation (31) satisfying Equations (29) may be obtained by assuming,

$$y = (A_1 \cos m_1 x + B_1 \sin m_1 x + A_2 \cosh m_2 x + B_2 \sinh m_2 x) \sin\left(\frac{2\pi t}{T} + q\right) \quad \text{(32)}$$

and properly determining the constants, m_1, m_2, A_1, B_1, A_2, and B_2. It is easily seen that Equation (32) is a solution of Equation (31) if m_1 and m_2 satisfy the

following equations:

$$m_1^4\, h^4 - \theta^2\, m_1^2\, h^2 - \frac{(\theta')^2}{u^2} = 0 \ldots\ldots\ldots\ldots\ldots\ldots (33a)$$

$$m_2^4\, h^4 + \theta^2\, m_2^2\, h^2 - \frac{(\theta')^2}{u^2} = 0 \ldots\ldots\ldots\ldots\ldots\ldots (33b)$$

Solving these two quadratics and noting that negative roots must be rejected because they give imaginary values of m_1 and m_2:

$$m_1^2\, h^2 = \frac{1}{2}\left(\sqrt{\theta^4 + \frac{4\,(\theta')^2}{u^2}} + \theta^2\right) \ldots\ldots\ldots\ldots\ldots (34a)$$

and,

$$m_2^2\, h^2 = \frac{1}{2}\left(\sqrt{\theta^4 + \frac{4\,(\theta')^2}{u^2}} - \theta^2\right) \ldots\ldots\ldots\ldots\ldots (34b)$$

By differentiation of Equation (32), expressions may be obtained for all the derivatives occurring in Equations (29). For conciseness, substitute $\frac{h'}{h} = c$, $\frac{(k')^2}{h^2} = e$, $m_1\, h = \alpha_1$, $m_2\, h = \alpha_2$, and replace $\frac{P}{E\,I}$ by $\frac{\theta^2}{h^2}$; then the resulting four equations for determining A_1, B_1, A_2, and B_2 may be written as follows:

$$A_1 + A_2 = a \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35a)$$

$$\alpha_1\, B_1 + \alpha_2\, B_2 = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35b)$$

$$\begin{aligned} &[\theta^2 \cos\alpha_1 + (u^2\,\alpha_2^2 - c\,\theta^2)\,\alpha_1 \sin\alpha_1]\, A_1 \\ &+ [\theta^2 \sin\alpha_1 - (u^2\,\alpha_2^2 - c\,\theta^2)\,\alpha_1 \cos\alpha_1]\, B_1 \\ &+ [\theta^2 \cosh\alpha_2 + (u^2\,\alpha_1^2 + c\,\theta^2)\,\alpha_2 \sinh\alpha_2]\, A_2 \\ &+ [\theta^2 \sinh\alpha_2 + (u^2\,\alpha_1^2 + c\,\theta^2)\,\alpha_2 \cosh\alpha_2]\, B_2 = 0 \ldots\ldots\ldots (35c) \end{aligned}$$

$$\begin{aligned} &[u^2\,\alpha_1^2 \cos\alpha_1 - (c\,u^2\,\alpha_1^2 + e\,\theta^2)\,\alpha_1 \sin\alpha_1]\, A_1 \\ &+ [u^2\,\alpha_1^2 \sin\alpha_1 + (c\,u^2\,\alpha_1^2 + e\,\theta^2)\,\alpha_1 \cos\alpha_1]\, B_1 \\ &- [u^2\,\alpha_2^2 \cosh\alpha_2 + (c\,u^2\,\alpha_2^2 - e\,\theta^2)\,\alpha_2 \sinh\alpha_2]\, A_2 \\ &- [u^2\,\alpha_2^2 \sinh\alpha_2 + (c\,u^2\,\alpha_2^2 - e\,\theta^2)\,\alpha_2 \cosh\alpha_2]\, B_2 = 0 \ldots\ldots (35d) \end{aligned}$$

Forced Oscillation of Known Period.—The coefficients of A_1, B_1, A_2, and B_2 in Equations (35) depend upon the constants of the oscillating system and also upon the period. For an oscillation of known period and amplitude the four unknowns may therefore be determined by direct solution of the four linear equations.

Free Oscillation.—The case of free oscillation also is covered by the foregoing solution as the limiting case, $a = 0$. In this case, however, u is one of the unknown quantities to be determined by Equations (35); moreover, these equations determine only the ratios of the four constants, A_1, B_1, A_2, and B_2, their actual values being indeterminate even after u becomes known. The elimination of these four quantities results in an equation involving the single unknown, u. (One method of expressing this equation is to equate to zero the determinant of the coefficients of A_1, B_1, A_2, and B_2.) Since both α_1 and α_2 depend upon u, the only practicable method of solving such an equation is to substitute trial values of u. After u is known, any one of the four constants, A_1, B_1, A_2, and B_2, may have an arbitrary value, the other three being expressed in terms of it; this means merely that the amplitude of the free oscillation remains arbitrary.

Because of algebraic complexity the general formulas resulting from the solution of Equations (35) when u is given, are here omitted; but the procedure above outlined will be illustrated by means of an assumed set of numerical data. First, however, will be shown the form assumed by the general solution when certain simplifying assumptions are made.

UNLOADED COLUMN

If $P = 0$, the problem reduces to that solved in the main part of this paper. This case is mentioned merely to emphasize the fact that the solution of that problem is covered as a particular case by the foregoing more general solution. Thus, if $\theta = 0$, and if $m_1 = m_2 = m$, Equations (33) reduce to a form which is identical with Equation (10). If, now, in Equations (35), $\theta = 0$, $c = 0$, $e = 0$, and $\alpha_1 = \alpha_2 = m\,h$; are substituted, these equations reduce to Equations (11).

SOLUTION WHEN INERTIA OF COLUMN IS NEGLECTED

For a given mass element, the effect of inertia upon the oscillation of the system is greater the greater the distance of the element from the ground. There may well be cases, therefore, in which the effect of the load, P, so far predominates that the inertia of the column itself may be treated as negligible. The simplified form assumed by the solution in such a case will now be given.

The differential Equation (31) reduces to the form,

$$\frac{\partial^4 y}{\partial x^4} + \frac{\theta^2}{h^2}\frac{\partial^2 y}{\partial x^2} = 0 \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

and a solution satisfying the boundary conditions, Equations (29), may be written in the form,

$$y = (A_1 \cos m\,x + B_1 \sin m\,x + A_2 + B_2\,x) \sin\left(\frac{2\,\pi\,t}{T} + q\right) \ldots (37)$$

It is easily seen that this satisfies Equation (36) if $m\,h = \theta$; and that the substitution of the proper derivatives in Equations (29) gives four equations for determining A_1, B_1, A_2, and B_2. Omitting details of algebraic transformation, the four equations may be written as follows:

$$A_1 + A_2 = a \ldots\ldots\ldots\ldots\ldots\ldots (38a)$$

$$B_1\,\theta + B_2\,h = 0 \ldots\ldots\ldots\ldots\ldots\ldots (38b)$$

$$(1 - \cos\theta + c\,\theta \sin\theta)\,A_1 + (\theta\,u^2 + \theta - \sin\theta + c\,\theta - c\,\theta\cos\theta)\,B_1 - a = 0 \ldots\ldots (38c)$$

and,

$$((c\,\theta \sin\theta - \cos\theta)\,u^2 + e\,\theta \sin\theta)\,A_1 - ((c\,\theta\cos\theta + \sin\theta)\,u^2 - e\,\theta + e\,\theta\cos\theta)\,B_1 = 0 \ldots\ldots (38d)$$

Equations (38) correspond to Equations (35) of the general solution; but in Equations (38) the solution for the unknown quantities has been partly carried out by the elimination of A_2 and B_2 from Equations (38*c*) and (38*d*).

Forced Oscillation.—If a is not 0, Equations (38) may be solved directly for A_1, B_1, A_2, and B_2, so that all the constants in Equation (37) become known in terms of a and u. This completes the solution for a forced oscillation of given amplitude and period.

Free Oscillation.—If $a = 0$, Equations (38) can be satisfied only for restricted values of u. In this case u must satisfy the following equation, obtained from Equations (38*c*) and (38*d*) by eliminating A_1 and B_1:

$$\theta\,(c\,\theta \sin\theta - \cos\theta)\,u^4 + (\sin\theta - \theta\cos\theta + (c + c^2 + e)\,\theta^2 \sin\theta)\,u^2 + e\,\theta\,(\theta\sin\theta - 2 + 2\cos\theta) = 0 \tag{39}$$

An example with numerical data, illustrating this case, will be given subsequently.

SOLUTION WHEN GRAVITY EFFECT IS WHOLLY NEGLECTED

In the foregoing theory both the inertia effect and the gravity effect of the load P have been taken into account, although the gravity effect of the column itself has been treated as negligible. In order to estimate the relative importance of the two effects for the load P, it will be useful to give a solution in which the gravity effect is neglected. This effect for the load P is represented by the term containing θ in Equation (31) and by the last term in Equation (36). Consider the result of omitting these terms, still treating the inertia of the column as negligible.

The differential equation becomes,

$$\frac{\partial^4 y}{\partial x^4} = 0 \tag{40}$$

The boundary conditions at $x = 0$ are unchanged, and the conditions at $x = h$ are still expressed by Equations (27), omitting the last term of Equation (27*b*); the value of V_1 to be substituted in these equations must be determined from the relation $V = -\dfrac{\partial M}{\partial x}$. This affects only Equation (29*c*), from which the term containing P in the second member must be omitted.

The appropriate solution is expressed by the following equations:

$$y = (A_0 + A_1 x + A_2 x^2 + A_3 x^3) \sin\left(\frac{2\pi t}{T} + q\right) \tag{41}$$

$$A_0 = a \tag{42a}$$

$$A_1 = 0 \tag{42b}$$

$$(1 + 2c)\,\theta^2 A_2 + (6u^2 + (1 + 3c)\,\theta^2)\,A_3 h + \frac{\theta^2 a}{h^2} = 0 \tag{42c}$$

and,

$$2\,(u^2 - e\,\theta^2)\,A_2 + 3\,(2\,(1 + c)\,u^2 - e\,\theta^2)\,A_3 h = 0 \tag{42d}$$

Forced Oscillation.—When a is not zero, Equations (42) determine A_0, A_1, A_2, and A_3 in terms of a, u, and the constants of the system, thus completing the solution for a forced oscillation of any known period and amplitude.

Free Oscillation.—If $a = 0$, u is restricted to values satisfying the following equation, which results from the elimination of A_2 and A_3 between Equations (42*c*) and (42*d*):

$$12\,\frac{u^4}{\theta^4} - 4\,(1 + 3\,c + 3\,c^2 + 3\,e)\,\frac{u^2}{\theta^2} + e = 0 \quad \text{.........} \quad (43)$$

It is noteworthy that Equation (43) makes u directly proportional to θ, their ratio depending solely upon the constants, c and e. Remembering the meanings of u and θ, this result shows that the free period is proportional to $\sqrt{\frac{P\,h^3}{E\,I}}$. It is of interest to compare this result with Equation (14).

SOLUTION WHEN SUPPORTED LOAD IS TREATED AS A PARTICLE

If the dimensions of the load are small in comparison with the length of the column, a sufficiently close approximation may be obtained by treating the load as a heavy particle. Algebraically, this amounts to assuming c and e to be zero, and results in material simplification of the formulas obtained in the foregoing solutions. In the general case defined by Equations (30) to (35), inclusive, in which the inertia of the column is taken into account, the case of free oscillation must still be solved by trial, and the value of u will depend upon both P and W. When the inertia effect of the column is neglected, however, the formulas become very simple, Equations (39) and (43), respectively, taking the following forms:

$$(\theta \cos \theta)\, u^4 - (\sin \theta - \theta \cos \theta)\, u^2 = 0 \quad \text{............} \quad (44a)$$

and,

$$12\, u^4 - 4\, \theta^2\, u^2 = 0 \quad \text{....................} \quad (44b)$$

Disregarding the zero roots, Equation (44*a*) gives $u^2 = \frac{\tan \theta}{\theta} - 1$; and Equation (44*b*) gives $u^2 = \frac{\theta^2}{3}$. A comparison of these results shows the effect of gravity upon the period of free oscillation. That this effect increases with θ, but is relatively small for small values of θ, may be seen by developing $\tan \theta$ in a power series giving,

$$\frac{\tan \theta}{\theta} - 1 = \frac{\theta^2}{3} + \frac{2\,\theta^4}{15} + \cdots \quad \text{..........................} \quad (45)$$

Since the definition of u (Equation (30*c*)) gives,

$$T = 2\,\pi\, u \sqrt{\frac{h}{g}} \quad \text{..........................} \quad (46)$$

Equations (44) yield the following formulas for T_0 for the oscillating particle:

Taking account of gravity effect,

$$T_0 = 2\,\pi \sqrt{\frac{\tan \theta}{\theta} - 1}\, \sqrt{\frac{h}{g}} \quad \text{................} \quad (47a)$$

neglecting gravity effect,

$$T_0 = \frac{2\,\pi\,\theta}{\sqrt{3}}\sqrt{\frac{h}{g}} \quad \text{(47b)}$$

FLEXURE OF COLUMN UNDER STATIC LOAD

It is of interest to note that the foregoing theory includes, as a special case, the theory of flexure of a column under a static load, commonly known as Euler's theory. For a column fixed at the bottom and free at the top, sustaining a centrally applied load, P, the Euler formula for incipient flexure may be written:

$$h\sqrt{\frac{P}{E\,I}} = \frac{\pi}{2} \quad \text{(48)}$$

In the foregoing oscillation theory the static case is the limiting case, $T_0 = \infty$, which, in Equation (47a), gives $\theta = \frac{\pi}{2}$, agreeing with the Euler formula by the definition of θ (Equation (30a)).

NUMERICAL APPLICATION

Assume the following numerical data for the purpose of illustrating the application of the formulas obtained in the foregoing theory, giving special attention to the case of free oscillation.

Example 1.—Assume that $\frac{h'}{h} = c = 0.3$; $\frac{k'}{h} = 0.2$; $e = \left(\frac{k'}{h}\right)^2 = 0.04$; $h\sqrt{\frac{P}{E\,I}} = \theta = 1$; and $W = P$, so that $\theta' = \theta = 1$. These values must be substituted in Equations (34) and (35); the former gives:

$$\alpha_1^2 = m_1^2\,h^2 = \frac{1}{2}\left(\sqrt{1 + \frac{4}{u^2}} + 1\right) \quad \text{(49a)}$$

and,

$$\alpha_2^2 = m_2^2\,h^2 = \frac{1}{2}\left(\sqrt{1 + \frac{4}{u^2}} - 1\right) \quad \text{(49b)}$$

Thus, for a given value of T (which fixes u), α_1 and α_2 become known and the coefficients of A_1, B_1, A_2, and B_2 in Equations (35) may be computed; the solution is thus easily completed for a forced oscillation of any given period and amplitude. For the case of free oscillation, however, u is not given, but must have a value such that Equations (35) can be satisfied when $a = 0$; such values can be found only by trial as indicated under the heading "General Solution." The trial solution involves considerable labor and the details will be omitted. It is found that the required condition is satisfied to a close approximation by $u^2 = 2.507$. By Equation (46), this value of u gives, as a possible value of the free period, $9.95\sqrt{\frac{h}{g}}$.

Example 2.—Assuming the same values of c and e as in Example 1, let $\theta' = 0$ (that is, neglect the inertia of the column). The period of free oscillation is computed: (*a*) for $\theta = 1$; (*b*) for $\theta = 0.25$; and (*c*), for $\theta = 0.1$. Substitution in Equation (39) gives the following:

$$(a)\quad u^4 - 2.3032\,u^2 + 0.010828 = 0$$

$$u^2 = 2.298 \quad \text{or} \quad 0.00471$$

$$T_0 = 9.53\sqrt{\frac{h}{g}} \quad \text{or} \quad 0.431\sqrt{\frac{h}{g}}$$

$$(b)\quad u^4 - 0.04977\,u^2 + 0.00001364 = 0$$

$$u^2 = 0.04949 \quad \text{or} \quad 0.0002757$$

$$T_0 = 1.398\sqrt{\frac{h}{g}} \quad \text{or} \quad 0.1043\sqrt{\frac{h}{g}}$$

$$(c)\quad u^4 - 0.007684\,u^2 + 0.000000335773 = 0$$

$$u^2 = 0.007640 \quad \text{or} \quad 0.00004395$$

$$T_0 = 0.549\sqrt{\frac{h}{g}} \quad \text{or} \quad 0.0417\sqrt{\frac{h}{g}}$$

Example 3.—With the same data as in Example 2, let the gravity effect of P be neglected. The value of u for free oscillation is now determined from Equation (43) which becomes, $12\frac{u^4}{\theta^4} - 9.16\frac{u^2}{\theta^2} + 0.04 = 0$, giving $\left(\frac{u}{\theta}\right)^2 = 0.7589$ or 0.004392; and for the three specified values of θ,

$$(a)\quad T_0 = 5.473\sqrt{\frac{h}{g}}, \quad \text{or} \quad 0.416\sqrt{\frac{h}{g}}$$

$$(b)\quad T_0 = 1.368\sqrt{\frac{h}{g}}, \quad \text{or} \quad 0.1041\sqrt{\frac{h}{g}}$$

$$(c)\quad T_0 = 0.547\sqrt{\frac{h}{g}}, \quad \text{or} \quad 0.0416\sqrt{\frac{h}{g}}$$

Example 4.—With each of the three values of θ used in Examples 2 and 3, determine the free period on the assumption that P is a particle. The simplified formulas, Equations (44) to (47), give the following results:

If gravity effect is taken into account,

$$(a)\quad \text{For } \theta = 1, \qquad u^2 = 0.5574, \qquad T_0 = 4.691\sqrt{\frac{h}{g}};$$

$$(b)\quad \text{For } \theta = 0.25, \qquad u^2 = 0.02137, \qquad T_0 = 0.9186\sqrt{\frac{h}{g}};$$

$$(c)\quad \text{For } \theta = 0.1, \qquad u^2 = 0.003347, \qquad T_0 = 0.3635\sqrt{\frac{h}{g}}.$$

If gravity effect is neglected,

$$(a)\ \text{For } \theta = 1, \qquad u^2 = 0.3333, \qquad T_0 = 3.628\sqrt{\frac{h}{g}};$$

$$(b)\ \text{For } \theta = 0.25, \qquad u^2 = 0.02083, \qquad T_0 = 0.9067\sqrt{\frac{h}{g}};$$

$$(c)\ \text{For } \theta = 0.1 \qquad u^2 = 0.003333, \quad T_0 = 0.3628\sqrt{\frac{h}{g}}.$$

Summary of Computed Results.—The results computed in Examples 2, 3, and 4 are summarized in Table 1, in which the tabulated numbers are proportional to the values of the free period for the several cases. The tabulation brings out clearly the fact that the importance of the gravity effect decreases as θ decreases.

TABLE 1.—VALUES OF $2\pi u$ IN EQUATION (46)

θ	$c = 0.3, \quad e = 0.04$		$c = 0, \quad e = 0$

DISCUSSION

Homer M. Hadley,[5] Assoc. M. Am. Soc. C. E. (by letter).—Any designer undertaking to design an entire structure or an individual part thereof is confronted, at the very outset of his labors, with the question of loading. To what loads will his structure be subjected; what is their magnitude; their direction; their point of application; their duration; their periodicity, etc.?

It is refreshing, therefore, to read the authors' admirable statement of the nature of the movements that cause and create the earthquake loadings (see paragraph preceding "Earthquakes and Their Effects: Relation to Structures" in Part I).

This is a plain, true description of the earthquake movements of the ground which every seismographic record ever taken clearly attests. A veritable chaos of confused, conflicting movements follows upon the primary initial disturbance, which may occur—who knows when, or how? The authors state (see "The Problem"): "It would appear to be beyond the ability of any mathematician to develop formulas that would take accurate account of the extremely variable nature of the factors involved." Assuredly this is so.

To the writer it has always seemed a waste of effort to use methods of design more refined than basic conditions warrant, and the clear presentation, in this paper, of the utter ignorance there is of the earthquake loading, prompts the suggestion that structural engineers may well recognize the limitations of their knowledge. When the magnitude and direction of the loads is unknown, what choice is there between a dynamical or statical approach to a solution as arbitrary as, and no more valuable than, the good guesses called assumptions made at the outset?

In the short insert appendix to his book "Earthquake Damage and Earthquake Insurance" the late John R. Freeman, Past-President and Hon. M. Am. Soc. C. E., gives "Some After-Thoughts by J. R. F. and a Few Notes from the Suyehiro Lectures."[6] The views summarized therein are most interesting and valuable, particularly the concluding paragraphs containing the suggestion—originating with Professor Suyehiro, a former naval architect—that quite as sea-going ships are designed successfully by assuming them to be riding on "standard" waves without knowing much about the actual waves and quartering seas which they encounter, so similarly one may, arbitrarily and successfully, design buildings against earthquakes by assuming a conventionalized loading. The fact that buildings in Tokyo designed under "the $0.1g$ basis" resisted the 1923 earthquake fairly well is called "a datum more valuable than any other arguments."

It would seem desirable, therefore, to adopt as design procedure nothing more complicated or involved than the assumption of horizontal forces acting in any direction upon the structure and applied at its base. Logically and properly, the magnitude of these forces is a function of the weight of the structure and its loads: $0.10g$, $0.08g$, or whatever judgment dictates. The damping effect which the height of very tall buildings has upon stresses may be recognized by using a smaller coefficient of g; or, as Mr. Freeman suggests, by model experimentation on a shaking table and special treatment. The important consequence of a design developed on this basis is not that computed stresses will be those actually developed in an earthquake, but that reversals of stress will be provided for, connections will be connections, anchorages will be adequate. All the sorry structural spectacles that have characterized past earthquakes have not been consequent upon the failure to use this or that cunning formula or method of design. They have been due to failure to provide proper resistance to horizontal forces even roughly approximate to those occurring.

---

[6] *Proceedings*, Am. Soc. C. E., May, 1932, Part 2.

Some additional comment may be offered on certain minor points. The authors state ("Earthquakes and Their Effects: Relation to Structures," in Part I) that since the forces generated in a structure subjected to earth movements are measured by the mass or weight of the building it follows that "the use of light materials in a structure is the best and that heavy, inelastic materials should be avoided as far as possible." Actually what follows is that with light materials the forces generated in a structure are of less magnitude than those developed with heavy materials. This is not, however, a criterion by which to assess the relative worth of the two constructions. Certainly on the basis of cost to the owner it may well prove more economical to specify the heavier material; and since the earthquake behavior of a structure does not result from the inert, lifeless materials of which it is built, but from the manner in which these materials are shaped and assembled and are combined together, it is not apparent that the weight of the construction has any appreciable bearing on the matter at issue.

Inasmuch as buildings "with wings at right angles" may be so built and connected as to sustain no earthquake damage, it is suggested that the paragraph dealing with the form of the structure be modified so that it indicates the hazards and dangers of this shape rather than pronounces inevitable doom. There is an almost equal hazard and danger in a square or rectangular building wherein the resistance to horizontal forces is most unequally and unsymmetrically distributed with respect to the plan of the building.

Regarding "visible surface waves" in the ground, to the writer (who has never chanced to see them), it has always seemed quite strange that they should occur without causing a general and extensive shattering of concrete sidewalks, curbs, etc. He has seen the rupturing of concrete pavements at fissures; but the waves, if any, apparently do no damage. In the fall of 1923 in Tokyo, a friend of the writer was in the Imperial Hotel when one of the countless aftershocks occurred. This was a very severe one, however, and it caused considerable alarm. Telling about it in the calm of the evening, he said that he had rushed to the window of his room, and looking out, it seemed as if the long side-wall of the hotel was "waving like a flag in the wind." He did not believe that the wall did wave, but he asserted that it seemed to. Bricks and concrete being intact, the phenomenon undoubtedly was a personal one—"in my mind's eye, Horatio."

R. McC. Beanfield,[7] M. Am. Soc. C. E. (by letter).—This paper is helpful and thought-provoking and will tend no doubt to stimulate interest in this important subject, which has been somewhat neglected by the profession in general. The paper contains much reiteration of known data; Part II, covering stresses and dynamic theory, treats the subject more from an academic point of view, and fails to offer any practical solutions. It also fails to include much advanced development in the art of aseismic design subsequent to 1928. The fact is that many engineers are mindful of the inadequacy or incompleteness of the theory and practice relative to aseismic design. The present state of the art is rather empirical and is based to a large extent on opinions and conjectures which are not substantiated by fact. Engineering is essentially a constructive art, and builds from known facts.

The following fundamental facts have been developed by scientific research, structural dynamics, and experimental investigation:

(1) When a vibratory motion is applied to the support of a system, the system itself will generally begin to vibrate. In the early stages of its vibration the motion of the system does not bear a simple relation to that given to the support. During this interval, the resulting motion is made up of two parts: "Free," or transient, vibrations; and "forced," or steady-state, vibrations. If the system is initially at rest when the disturbing motion begins, free vibration will always exist during the early part of the motion. These transient vibrations may cause the displacements of the structural system to be more than twice as great as those that will eventually exist in the steady state.

(2) Earthquake motion is not simple motion even if one dimension is considered. It consists of elastic impacts followed by free vibration and forced vibration with all their transients superimposed. The period, or apparent period, varies throughout the duration of the earthquake although in a number of actual, strong-motion seismographs certain periods dominate.

(3) Seismic ground vibrations (in so far as records to date reveal them) are not harmonic; on the other hand, the vibration of elastic yielding structures, caused by the disturbing force of seismic impulses, is harmonic, which fortunately tends to simplify the dynamic problem.

(4) The presence of transients may cause very high stresses within the duration of the first cycle or the first two cycles of the disturbing motion, which indicates that earthquakes do not require sustained vibrations in order to cause dangerous stresses in structures. Displacements of an oscillating structure are directly proportional to the ground amplitude. Therefore, the structure may be out of resonance with the ground and yet be over-stressed because of the large amplitude of the ground motion. Earthquake periods need not be in direct resonance with the natural periods of a structure in order to produce dangerous dynamical stress effects.

(5) The application of a fictitious or supposititious static force, derived from the conventional formula $H = \frac{W\alpha}{g}$ (wherein a maximum acceleration of the ground is assumed to be the same through all parts of the structure above the ground), may be used to obtain a practical solution only for relatively stiff

---

[7] Cons. Engr., Los Angeles, Calif.

structures such as one-story or two-story block-type buildings of average height. Its use as a general formula for aseismic design in elastic yielding structures such as water-towers, chimneys, multi-story frames, etc., is unscientific and may result in a false sense of security and structural stability.

(6) The conventional measure of the intensity of the earthquake known as the seismic factor is the ratio of the greatest horizontal acceleration of the ground to the acceleration due to gravity. It is a well-established fact that the only proper method of judging earthquake intensity is by the kinetic energy method. It can be demonstrated by structural dynamics that the kinetic energy decreases as the frequency increases, or as the period shortens, and that the amplitude of motion decreases very much faster than the frequency increases. These results prove that the acceleration used in the conventional statical formulas is not a constant and loses its usefulness as a measure of the intensity of the earthquake. It is irrational to assume a single constant value of the intensity ratio or seismic factor independent of the periods.

(7) The natural period of a structure is a criterion of its rigidity.

(8) Dampening has little effect in reducing the maximum amplitude of the transient vibration and possible dangerous stresses during the first few cycles of vibration. The stiffening effects due to the friction of joints and of interior secondary partitions, such as plaster, wood, or tile, should not be given any value in computing displacements of the structural frame.

(9) Elastic yielding structures, particularly the more flexible type, do not always vibrate only in their fundamental modes. As a matter of fact the motion of the ground causes harmonics of frequencies higher than the fundamental, and there is always the probability that one of these harmonics, usually within the first five modes, is close enough to the ground oscillation to cause dangerous dynamic forces. In the more elastic types of structures, such as towers, the maximum natural period is limited by conditions of buckling.[8]

The statement in the paper (see heading "Dynamic Theory as a Guide to Practical Design"), that the solution on the assumption of rigidity is simple and definite, may be questioned. The structural designs, in which a fictitious horizontal static force is used, do not comprise a simple problem. As a matter of fact, in order to obtain similar rigidities throughout the structure, considerable ingenuity and a good practical knowledge of the application of the elastic theory are required.[9]

The "Fundamental Practical Rule," which the authors infer can be used with confidence (see "Dynamical Theory as a Guide to Practical Design"), does not apply to all types of structures. It should be understood definitely, and emphasized, that this rule applies only to inherently rigid structures, such as one-story or two-story buildings that have natural periods of exceedingly high frequencies.

Attention is called to a common error in the use of the fixed-force method wherein the horizontal force or supposititious shear (used, for example, at each floor level in a structural frame) is based on a constant value of the maximum ground acceleration, usually 0.1 g, whereas the actual acceleration at each floor level varies and increases from the ground up. It is obvious that, as the deflection increases upward, so does the acceleration.

---

[8] "Die Erbebensicherheit von Bauwerken," by Dr. R. Briske.

[9] "Earthquake-Resisting Construction," by Dr. T. Naitō.

All structures that are elastic yielding should be designed by some method of dynamic analysis. In this connection the writer suggests the following method.[10]

(a) Compute the natural period of the structure by determining the maximum deflection or displacement due to horizontal disturbing forces based on the seismic factor of 0.1 g. If the maximum deflection of an elastic structure within its elastic limit is known, then, by structural dynamics, the maximum period, acceleration, and dynamical shears can be obtained. The maximum statical deflection of an elastic structure is also approximately the maximum amplitude of its transient vibrations.[11]

(b) By the use of the magnification factor B, the maximum stresses, which should not exceed the elastic limit, can be determined by the formula

$$B = \frac{1}{1 - \frac{T_0^2}{T^2}} \dots\dots\dots\dots\dots\dots (50)$$

in which T_0 = natural period; T = period of disturbing forces; and, B = index of the increase in deflections, bending moments, and stresses due to forced vibrations.

(c) The natural period of a structure ascertained by the foregoing method should not exceed 0.5 sec.

It is an established fact that the dynamic responses of structures to earthquakes of high frequencies or short periods do not have large displacements of amplitude. Therefore, structures with high frequencies will not be dangerously affected, and it is also true that the duration of seismic frequencies is usually short.

Attention should be called to the fact that application of the various formulas based on the dynamic analysis of a thin rod of constant cross-section, even for comparative purposes, in the design of structures, may lead to erroneous and dangerous results. In a number of the flexible structures such as chimneys and towers, for example, the mass of these structures is not usually uniform, the moments of inertia vary, and the deformation is caused more by shear than by bending moments. For instance, the deformation of structural frames is due more to shear which completely changes the formula of the thin rod concept. Therefore, it is not applicable to such structures. "Formulas are the anesthetics of thought, not its stimulants."

What Materials Should Be Used?—Invariably, buildings are described as brick, concrete, or steel-frame structures. It must be emphasized that it is not the materials but the design that is of foremost importance. There are certain requisites for materials, and certain materials fit these particular requirements better than others. As to this suitability, there has been much ignorant propaganda and some deliberate misrepresentation. If the engineer will prepare a design and compute the stresses, he will see for himself which materials are required for a given place in the structure.

[10] "Vibrations and Their Effects on Structures," by R. McC. Beanfield, Applied Science Div., Local Section, A. S. M. E., Los Angeles, Calif., April 25, 1934.

[11] "Vibrational Problems in Engineering," by S. Timoshenko, Rayleigh's Energy Method, p. 63.

R. S. Chew,[12] M. Am. Soc. C. E. (by letter).—It is thirty years since the writer offered a paper which dealt with this subject.[13] The analysis is crude and has several apparent errors; and yet the treatment of the stiff structure is similar to that suggested in Section II of the present paper, under the heading "Fundamental General Rule."

The analysis of the flexible structure was not attempted by the writer except to indicate reversal curves for both a uniformly flexible structure and the flexible first story. In later years the writer has realized that the foregoing treatment was insufficient and has made an analysis of the problem assuming the structure to have its base oscillating horizontally, with simple harmonic motion, and has published a monograph on this subject.[14]

From the foregoing it will be appreciated that the writer has read the rigid analysis presented in this paper with keen interest and believes it will be of great value to the profession in its study of the problem. The writer hopes that the treatment will be extended so that it will reveal the condition in which $\frac{T_0}{T}$ varies from 1.6 to 4.0 because he believes in a zone of $\frac{T_0}{T}$ between 1.6 and 4.0. The characteristic curves will appear as reverse curves with nodal points. This is necessary in the consideration of higher buildings in which periods of 1.35 to 1.8 are usual. In the writer's treatment[15] he has attempted to indicate the deformations in this zone.

Turning from theory to a practical consideration, it is to be noted that the value of T_0 is ambiguous.

The authors state that Equation (14) may give some indication of the order of magnitude of period for a tall building. On the other hand, it is impractical to evaluate $E\,I$ in a building when walls (fire-proofing), partitions, and frame must all be considered as acting.

In the thirty-three years since 1906 the writer has observed the rebuilding of San Francisco, Calif., with structures having a marked difference in the amount and type of bracing, and has made a relative study of measured periods of the tall buildings ranging from seventeen to twenty-nine stories in this city. On the basis of this study he has reached the opinion that at least 50% of the stiffness in a wind-braced, wall-enveloped, tall building, with usual office windows, is due to wall and fire-proofing, etc.

From records of the Japanese it was found that the period of a structure lengthens during a base movement due to the loosening and cracking of the non-elastic materials—and from measurements before and after an earthquake, it has been stated[16] that the increase varies from 30 to 50 per cent. This indicates that the structure passes through several period states until the various resistances produce a period that maintains. Consequently, the period T_0 must be assumed from comparison with existing structures of known period; or it must be based on some empiric formula.

[14] "An Approximate Measure of Earthquake Effect on Framed Structures," by R. S. Chew; published privately by the author at San Francisco, Calif., 1938; a copy has been filed for reference in Engineering Societies Library, 33 W. 39th Street, New York, N. Y.

[15] *Loc. cit.*, p. 82.

[16] "Tests on Maronouchi Building in Tokio," by Tadasi Taniguti, *Paper no. 645*, *Transactions*, World Power Conference, Vol. 8, 1929.

The foregoing indicates why the writer is unable to subscribe to the authors' practical rule of

$$F = m\,\alpha = \frac{W}{g}\,\alpha \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (51)$$

when applied to all buildings, stiff or flexible. In fact the writer does not believe that any constant seismic factor is logical.

When applied to the frame the factor produces increased strength but only a small margin of stiffness, whereas stiffness is the required feature. It is understood that strength is necessary; but for the present problem it is sufficient to have a resilient body under the action.

For the purpose of illustration consider the practical problems involved in a six-story design and a twenty-five-story design, assuming the following factors as known and as actually resulting from earthquake acceleration equal to 3.2 ft per sec^2: Amplitude = 1 in.; and, period T = 1 sec. Both structures are to be designed under a specified load of $\frac{1}{10}W$ as a lateral force. The designer of the six-story structure will apply the factor giving the structure the necessary strength, but is likely to have a period T_0 of between 0.6 and 0.8 sec, in which case the structure actually has stresses 40% higher than called for by the factor.

Assuming that it is practical to apply the lateral force to the twenty-five-story building, the designer would have to add approximately 40% to his steel tonnage in order to meet the strength requirement; but it will be found that unless diagonal bracing is incorporated, the increased stiffness is not in proportion, and from the writer's study, the period would be decreased 10% to 15% below that of the 20-lb, wind-braced, structure.

It will be seen that the structure has changed its flexible characteristics very little, so that its deformation is approximately the same, in which case, although the building is stronger, it will probably suffer as much wall and partition damage as it would under a 20-lb wind design. These results are logical because the factor (0.1W) was based on a rigidity, which neither design possessed, under the action described. The stiffer building received the accelerated movement, increased by additional acceleration due to yield. The flexible structure absorbed the accelerated movement in its deformation.

From the writer's viewpoint the requirement by ordinance, for the foregoing, should have been: Acceleration = 3.22 ft per sec^2; and amplitude = 0.25 in., 0.50 in., or 1.0 in., depending on the soil, with corresponding periods, T, equal to 0.5 sec, 0.7 sec, or 1.0 sec, in which case the designs would have been more consistent.

Resonance.—In high flexible buildings the danger of resonance is remote due to the fact that an earthquake period is rarely, if ever, as great as the period of the loaded frame with damping removed.

In low stiff buildings $\left(\frac{T_0}{T} < 1\right)$ there is a danger of the period lengthening until it is approximately equal to T.

Damage.—There is no doubt that wall damage is unavoidable due to deformation except in such low structures (as to height and design) that their maintained period is less than 0.5 sec, in which case deformation is small.

Jacob J. Creskoff,[17] Esq. (by letter).—Under the headings "Dynamical Theory as a Guide to Practical Design: Fundamental Practical Rule" and "Danger of Resonance," the authors express some interesting conclusions. Since m equals $\frac{W}{g}$, the fundamental practical rule of the authors may be restated as:

$$F = W\frac{a}{g} = W\,K \qquad (52)$$

in which, W = weight, in pounds; and, K = a constant, varying from 0.02 to 0.10. Hence, the fundamental practical rule of the authors will be recognized as the basis of the statical method of aseismic design. Naturally, statical design is to be preferred to a system that disregards aseismic features. However, it should be kept in mind that, although some statically designed structures have reacted well during earthquakes, it has become increasingly apparent that survival in these cases has been largely a matter of chance.

The following factors are involved in most of the earthquakes that occur in the United States: Invisible elastic earth waves are generated by the slipping of contiguous fault-blocks. Upon reaching a certain location, these waves jar the site and its superimposed structures into vibration. The response of a particular building is determined by the complex relationship between the earth waves, the site, and building characteristics, but principally by the resonance or synchronism ratio between the dominant periods of the site and building. If the ratio approaches unity, the building will vibrate dangerously within a few seconds—only several vibrations. That synchronism is of profound importance in aseismic design has been demonstrated not only theoretically, as in the paper by the authors, but experimentally by Arthur C. Ruge, Assoc. M. Am. Soc. C. E.,[18] and others, and by analyses of actual earthquake damage. A. Blake has shown[19] that the periods of invisible earth waves may be of any values included in the entire range of building periods. One or more dominant periods may appear in a site vibrating by reason of the passage of these waves through it. Finally, the superimposed structure vibrates in a number of natural periods.

At first glance therefore it seems improbable that a practical rule for estimating the probable effects of synchronism can be formulated. However, the writer is of the opinion that (except for the improbable case of synchronism between the earth waves and the site) the degree of synchronism existing between the dominant site and building periods is a reliable index to the probable extent of stresses due to synchronism.

---

[17] Cons. Engr., New York, N. Y.

[18] "Earthquake Resistance of Elevated Water-Tanks," by Arthur C. Ruge, *Proceedings*, Am. Soc. C. E., May, 1937, p. 801.

[19] "The Recording of Strong Seismic Motion," by A. Blake, *Bulletin* of the Seismological Society of America, July, 1933, p. 111.

The dominant periods of a site can be determined by jarring it with dynamite blasts, or with a shaking machine, recording the vibrations by seismographs, and interpreting the records. The dominant periods of an existing building can be found by recording and interpreting its vibrations as caused by wind, or with a shaking machine. In the case of a projected building, the writer agrees with the authors that a designer is powerless to estimate the possible danger from synchronism unless he can compute the periods of vibration of the building. Fortunately, there is now (1936) available a wealth of observational data on building vibrations.[20] With the plans and loading of the building, the empirical data, and the available vibration equations, the designer can compute the periods of the projected building with reasonable accuracy.

For example, suppose that, as in the statical method, the horizontal force to be resisted by a building is assumed to be acting at right angles to the elevations of the building, at the foundation, floor, and roof levels, and calculated by the formula

$$F = W K \dots\dots\dots\dots\dots\dots\dots\dots (53)$$

in which F is the horizontal force acting at the section under consideration, in pounds; K is a numerical constant depending on dynamical and experimental considerations (see Table 2); W is the total dead load plus actual live load at, and above, the section under consideration, in pounds (minimum live load to be one-fourth the design live load); T_b is the period of vibration of the building, in seconds; and T_g is the period of vibration of the site, in seconds. The synchronism ratio $\frac{T_b}{T_g}$ that gives the largest value of K in the plane of vibration under consideration is to be used. The values of K given in Table 2 must be divided, however, by the order of the period of vibration (that is, the fundamental period will be divided by (1), the first harmonic by (2), etc.). The minimum value of K used for any building will be $K = 0.05$, except for public buildings, for which K is not less than 0.10.

TABLE 2.—VALUES OF K

Site Material	VALUES FOR THE FOLLOWING SYNCHRONISM RATIOS, $\frac{T_b}{T_g}$:									
	2.0	1.8	1.6	1.4	1.2	1.0	0.9	0.8	0.7	0.6
Bed-rock	0.05	0.06	0.07	0.12	0.21	0.30	0.25	0.12	0.07	0.05
Consolidated ground	0.05	0.07	0.08	0.13	0.23	0.33	0.28	0.13	0.08	0.05
Soft ground	0.05	0.05	0.06	0.09	0.15	0.22	0.19	0.09	0.06	0.05

The seismic force, $F = W K$, acts against the mass of a building. Assuming that the mass is concentrated at the floor levels, and that floors are horizontal girders that deflect as units, then the columns and beams between two consecutive floors may be regarded as vertical beams—deflecting equally because of a concentrated horizontal force acting against the upper floor—and with end fixities determined by the degree of fixity between the vertical beams and the floors. Under these assumptions, the seismic force is distributed to all of the vertical beams, and to each in proportion to its relative rigidity.

---

[20] *Bulletin No. 201*, U. S. Coast and Geodetic Survey.

It will be noted that the values of K given in Table 2 are frequently much larger than the maximum value described by the authors under their fundamental practical rule. This is to be expected, of course, since the values of K in the table reflect the influence of synchronism between site and building periods during an earthquake.

One might judge that the use of such high values of K would add materially to the cost of a structure. This might be the case if the frame of the building is to be designed for these large values of K. However, if, in addition to the frame, the walls and floor and roof slabs are designed to resist the seismic force, it has been the experience of the writer that these higher values of K will not affect, appreciably, the cost of the building as a whole.

Arthur C. Ruge,[21] **Assoc. M. Am. Soc. C. E. (by letter).**—This interesting paper draws attention to the great difficulties in the way of rational design against earthquakes. Certainly it is clear that a purely analytical approach to the problem is out of the question, except for such general and valuable qualitative information as that developed by the authors and several other writers on the subject. The natural tendency of the average designing engineer is to throw up his hands at the thought of making any dynamical analysis at all, and it is only through the persistence of these investigators that the subject is kept alive and with it the hope of an ultimate solution.

The writer would like to comment upon a few statements contained in the paper with a view to further clarification, rather than criticism, and to add some comments on the interpretation of forced vibration analyses like those presented by the authors.

It is clear that the authors recognize the importance of the transient response of structures, and that they regard the forced or steady-state response as only a guide to judgment in design. There is one important point, however, which seems to be quite generally overlooked in connection with the behavior of the higher modes of vibration. It will be found invariably that a considerably closer "tuning in" of earthquake frequency with natural frequency is required in the higher modes for the same degree of dynamic magnification; the higher the mode, the sharper the tuning must be.

This fact is well known to those who have had experience in generating the higher modes of vibration of mechanical systems or models. Many casual experimenters have had the mistaken notion that the effect is due to a greater degree of damping in the higher modes. Although in some cases there may be greater damping and an attendant reduction of magnification in the higher modes, the presence of damping will always tend to make the tuning less critical at resonance which, therefore, makes it impossible to explain the tuning phenomena observed on the basis of damping effects.

Physically, this means that the probabilities of damage in the lower modes are far greater than in the higher, simply because the degree of tuning is less critical in the lower modes. As an example, consider the ratio $\frac{V}{V_0'}$ (Equation

---

[21] Asst. Prof. of Eng. Seismology, Mass. Inst. Tech., Cambridge, Mass.

(18c)) at the base of the beam for the first and second modes; that is, the ratio of the actual shear at the base to the shear that would occur in a perfectly rigid structure of the same weight. The following data were obtained from Equation (18c):

Mode	$\frac{T_0}{T}$	$\frac{V}{V_0'}$
First.................	0.95	7.0
Second..............	0.98	4.6

That is, the earthquake period is 5% above the first mode resonance and 2% above the second mode. It is apparent that the tuning in at the second mode must be more than 2½ times as sharp as at the first or lowest mode in order to produce the same dynamic magnification. The effect becomes even more pronounced above the second mode. Now, it must be remembered that the foregoing data are not the actual shears but magnification factors—the shears are $V = 7.0\ V_0'$ and $4.6\ V_0'$; and it is here that a second and equally important consideration enters; namely, the actual values of V_0' decrease very definitely at the higher earthquake frequencies and hence at the higher modes of buildings. Exactly what law governs the variation of earthquake amplitude with frequency is not quantitatively known as yet, but the fact that the amplitudes do decrease with increase in frequency is too well known to be debated. Over very limited ranges the trend may be reversed; but when widely separated ranges are compared (as the first and second modes of a structure which may bear a 5 : 1 or a 6 : 1 period relation) one may confidently expect to find a large drop in amplitude in the range of the higher modes.

The natural conclusion, therefore, seems to be that the modes above the first (or, in rare structures, possibly the second) are not nearly so important as would be indicated by a superficial study of the steady state analysis. It is on the basis of such reasoning that the writer questions the statement (see Part II, under "Dynamical Theory as a Guide to Practical Design: Danger of Resonance") that: "Since any given structure has a multiplicity of natural periods, and since the harmonic analysis of seismograph records has shown a considerable range of values of T, it seems impracticable to formulate any simple rule for minimizing the probability of dangerous stresses due to resonance." It seems to the writer that by limiting the modes to be studied to one or, perhaps, two, the problem is not so hopeless as it might at first seem. The mere fact that difficulties still beset the investigator should not lessen the determination to achieve a full solution ultimately.

It is further true that the frequency selectivity of the higher modes may be augmented by proper design. Indeed, the introduction of a flexible first story has just such an effect, as may easily be visualized.[22] The only objectionable feature of this construction is that it increases, considerably, the liability of the first story to damage, due to the lowered period of the fundamental. The writer has yet to see a suitable and economically feasible design proposed for the first story of such structures.

---

[22] See "Experimentally Determined Dynamic Shears * * *," by L. F. Jacobsen, *Bulletin*, Seismological Society of America, Vol. 28, No. 4, October, 1938.

The statement (see Part I under "Earthquakes and Their Effects: Relation to Structures"), to the effect that the forces of the moving ground are unlimited, may require some modification. Although it is doubtless true for structures on rock and for light structures on compact soil, there is reason to believe that heavy structures resting on soil do not behave as if the ground motion were inexorable, but instead they influence the ground movement locally to a marked extent. Some evidence of this influence has been noted in the effects of the Japanese earthquake of 1923, and analytical studies by K. Sezawa and K. Kanai[23] lead to the same conclusion. Professor Jacobsen has also presented a valuable study of this phenomenon.[24]

In Part I (under "Earthquakes and Their Effects"), the authors express the limits of earthquake periods as 0.1 sec and 2 sec. This is a much disputed point, however, and there is reliable evidence that wave periods much longer than 2 sec occur in destructive earthquake motion.[25] In general, it appears that the more severe and extensive the quake, the more prominent become the long-period components of motion. This fact is of great importance and should receive careful consideration in connection with ground-period studies made by shaking machines and by observation of small earthquakes and blasts. A study of the Long Beach motion (integrated by the U. S. Coast and Geodetic Survey) shows a surprising amount of long-period motion. Of course, waves shorter than 0.1 sec occur, but the authors probably considered them of no structural importance. Perhaps this question might best be left open at present.

In Part I, the authors omit consideration of the possibilities of the experimental or semi-experimental approach to the problem of anti-seismic design. The writer believes that sufficient facilities exist for extending the knowledge of quake-resistant design to the point of practical significance by combining the experimental and analytical techniques effectively. The principal reason for the lag of accomplishment behind facilities has been, and is, the lack of adequate funds for establishing the requisite long-time basic research with adequate personnel. To say that the surface has only been scratched is to risk exaggeration, but the profession owes a debt of gratitude to those men who have pushed forward the theoretical analysis until the possibility of a practical solution may be seen.

Walter L. Huber,[26] **M. Am. Soc. C. E. (by letter).**—A basic assumption not mentioned in the authors' development of the equations for the vibration of an elastic cantilever is that the formulas hold only for the "steady state" condition—that is, the condition obtained only after a considerable interval of time has elapsed since the initial harmonic impulse. This one assumption alone, not including those pointed out by the authors, is difficult to substantiate in such an erratic ground movement as experienced during an earthquake. At the same time, since this "steady state" condition is not likely to be realized in an earthquake, it suggests the application of the impact theory as developed by Prof. Joseph N. Le Conte in 1926.[27] During earthquakes there is considerable evidence of failure due to impact. In reviewing the damage to the concrete stack of the Seal Beach Station of the Los Angeles Gas and Electric Corporation, due to the Long Beach earthquake of March 10, 1933, the application of Professor Le Conte's paper was studied as one line of analysis.

[26] Cons. Engr., San Francisco, Calif.

This stack, weighing about 2 800 tons, was 317 ft high, rising from a concrete platform which was, in turn, supported just beneath the roof on a steel framework. The base of the stack was about 65 ft above the ground. It was 24 ft in diameter at the top and 35 ft 6 in. in diameter at the base. The principal reinforcement consisted of vertical steel bars. Circumferentially only two layers of steel fabric were supplied for reinforcement. The stack suffered considerable damage in the earthquake, particularly in the middle third of its height, where many horizontal cracks opened. In certain places it appeared that such cracks had opened and had then come together. This was particularly noticeable where reinforcing steel appeared to have been first elongated and then compressed.

Determination of forces due to earthquakes to which complicated structures are subjected is not an easy task, and opinions advanced from such determinations are not always beyond question. On the roof of Seal Beach Station three 20 000-gal water-tanks would seem to afford opportunities for rather direct determinations. Even in this case, however, certain very essential information was not available. For instance, it was not known whether, at the time of the earthquake, the tanks were filled. It seems probable that two of them were not filled, but that the third one may have been, and probably was, approximately full. Assuming that it was filled and assuming the ultimate strength of certain rods in the tank frame which were broken by the earthquake to be 65 000 lb per sq in., the force necessary to have caused the destruction of these rods would have amounted to 27% of the force of gravity; or, if the ultimate strength of the rods were assumed equal to 70 000 lb per sq in., this force would have been 30% of the force of gravity. Of course, if the tank were not filled, the force exerted was a larger percentage of the force of gravity since in any case the rods were broken, and if the tank were not filled they would have been acting upon a smaller mass. These percentages must be considered the minimum force. It is not known how much this force exceeded that necessary to rupture the rods.

The tank in question was supported on the roof of the station about 65 ft above the ground. On this roof it is probable that both accelerations and displacements were considerably more than those of the ground beneath the station. Since the earthquake of June 10, 1933, instruments have been installed by the U. S. Coast and Geodetic Survey to record accelerations in the top stories and in the basements of several buildings in California. These instruments, although of the strong-motion type, are so connected that a movement sufficient to start one instrument will start both, thus giving simultaneous records. These instruments have shown (as in the case of a

[27] "The Stresses in a Free Prismatic Rod Under a Single Force Normal to Its Axis," by J. N. Le Conte, *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 968.

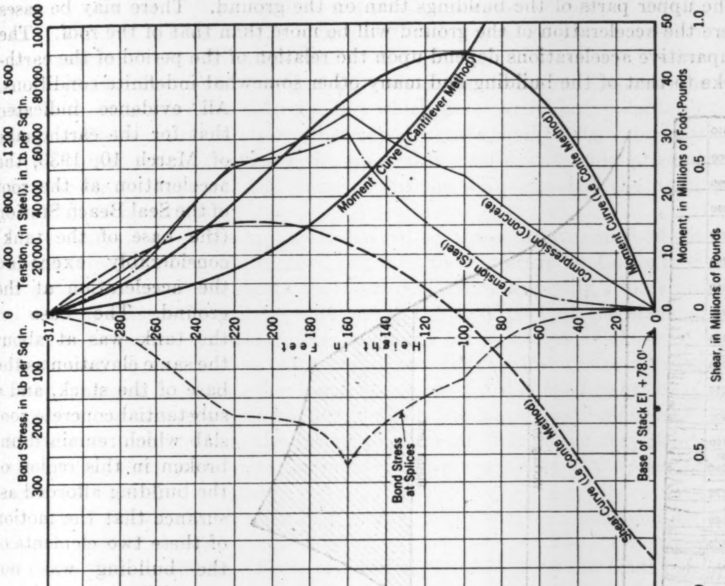

FIG. 7.—SEAL BEACH STACK; STRESSES BY LE CONTE METHOD

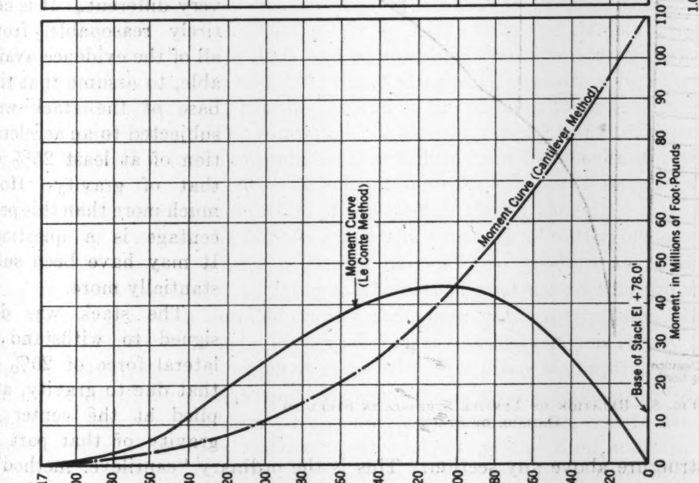

FIG. 6.—SEAL BEACH STACK; COMPARISON OF MOMENTS BY CANTILEVER AND LE CONTE METHODS

minor earthquake of June 25, 1933, for example) considerably more acceleration in the upper parts of the buildings than on the ground. There may be cases where the acceleration of the ground will be more than that of the roof. The comparative accelerations depend upon the relation of the period of the earthquake to that of the building and many other somewhat indefinite conditions.

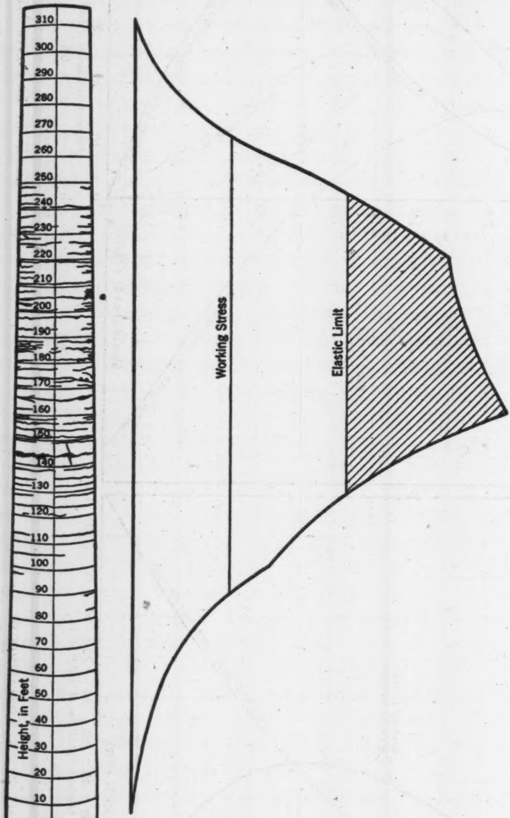

FIG. 8.—RELATION OF TENSILE STRESSES IN STEEL TO DAMAGE OF STACK

All evidence indicated that for the earthquake of March 10, 1933, the acceleration at the roof of the Seal Beach Station (the base of the tank) considerably exceeded the acceleration at the ground. The base of the tank was at about the same elevation as the base of the stack, and a substantial concrete roof slab which remained unbroken in this region of the building afforded assurance that the motion of these two elements of the building was not very different. It is entirely reasonable, from all of the evidence available, to assume that the base of the stack was subjected to an acceleration of at least 25% of that of gravity. How much more than this percentage is a question. It may have been substantially more.

The stack was designed to withstand a lateral force of 20% of that due to gravity, applied at the center of gravity of that part of the structure above any section. This is the ordinary "cantilever method"; and, although it is applicable if static loads or fundamental vibration forces are to be resisted, it is not in accordance with methods now commonly accepted for earthquake analysis of tall slender structures. Nor does it accord with observed destruction of such tall slender structures. Analysis in accordance with the "cantilever method" indicated that, for a force of 20% of gravity, the reinforcing steel would not be stressed beyond 16 000 lb per sq in. in tension, and the concrete, beyond 650 lb per sq in. in compression, which are conservative working stresses.

Professor Le Conte's method of analysis requires some assumptions which are not realized in their entirety, but which were particularly adaptable to this stack. These assumptions are that the structure shall be rigid, prismatic, and free of all support. Actually the stack was elastic, not truly prismatic, and had an elastic support, but these conditions approximated the assumptions required to be made.

A comparison of the moments derived by the cantilever method with those derived by following the method outlined by Professor Le Conte is shown in Fig. 6. The moments shown there are derived by applying a force of 25% of that of gravity. It will be noted that for that part of the stack near the base, the cantilever method gives moments far in excess of those of the Le Conte method, and it is also of interest to note that the lower part of the stack was little damaged. On the other hand, above one-third of the height the moments are found to be more than those for which the stack was designed—in places more than double. It is also interesting to note that at the very points where this analysis indicates largest moments and over-stressing of the steel, the stack suffered considerable damage.

Fig. 7 shows the stresses in the steel and concrete corresponding to the moments and shears obtained by the Le Conte method of analysis. For heights of from 150 to 225 ft, or from 47% to 71% of the total height, the tensile stress in the steel reinforcement was found to be more than 50 000 lb per sq in. and more than 60 000 lb per sq in. at a height of 160 ft, these stresses being beyond the elastic limit and approaching the ultimate strength of the material. It should be noted that unit stresses of steel are a function of the amount of steel actually supplied as well as the moment to be resisted—hence, the irregular curve. The computed bond stress ranged to as much as 266 lb per sq in., and it is not improbable that failure from this weakness resulted.

In Fig. 8 the very close agreement between computed stresses and the experienced cracking and failure of the stack is clearly shown.

Here is a practical example where the necessity of satisfying more than merely the laws of statics is clearly necessary to produce an earthquake-resistant structure. In applying mathematical analyses to this problem the writer was guided by detailed studies of damage by the earthquake, which is a test to be highly regarded. Every such mathematical analysis is only as valid as the assumptions on which it is based. Too often assumptions are made without a firm foundation, and thereafter the analyst is inclined to forget the doubts which troubled him when making the assumptions and to accept the results of the intricate mathematical analysis as the final solution of the problem. Although the stresses found in this investigation were, in all cases, considered to be approximate, the application of the theoretical analysis is substantiated by damage observed in careful and comprehensive inspections of the structure.

The theoretical analysis discussed herein did not enter into the problem of reconstruction because it was found necessary to remove a considerable part of the stack without replacing it. The problem was thus removed from the field of this analysis.

The experience noted was in accord with that of other stacks built on the tops of buildings and which have been subjected to earthquake shocks. Homer M. Hadley, Assoc. M. Am. Soc. C. E., in commenting upon damage resulting from the Japanese earthquake of September 1, 1923, states:[3]

> "Of all structures of reinforced concrete, chimneys gave the least satisfactory performance. When built up from the tops of buildings, they failed in all cases."

An attempt was made to apply the so-called "hammer theory" in an analysis of the stack, utilizing some of the work of Walter Ruppel, Assoc. M. Am. Soc. C. E.[8] By this theory moments somewhat larger than those heretofore enumerated in this discussion were found in the lower 90 ft of the stack, but these were all less than the moments for which this part of the stack was designed. Above this lower section, although following the same general shape, the moment curve showed somewhat smaller moments. This condition does not accord with observations of damage, although even in this case the vertical reinforcement was stressed beyond its elastic limit. It is the writer's opinion that the base of the particular stack under consideration did not have enough effect to make the "hammer theory" applicable.

It would be interesting to investigate the stack by means of the vibration theory developed by the authors, but this is not possible with available data. There is some difficulty in determining the period of ground motion from available seismograph records. These records verify the authors' statement (see Part I "Earthquakes and Their Effects") that:

> "The waves that damage structures are impressed waves, changing rapidly in period, amplitude and acceleration. Seismograms rarely show traces of harmonic waves, or those with regular characteristics. This is probably a very fortunate circumstance because it prevents, to a large extent, the resonance of vibrating structures."

In the present case, there is even less information to indicate the period of motion at the roof of the power-house, or the base of the stack.

A. A. EREMIN,[28] ASSOC. M. AM. SOC. C. E. (by letter).—The moment of inertia of mass has a negligible effect on the distribution of earthquake stresses in the vertical long (compared with transverse dimension) beam, as correctly stated in the paper. Likewise, one may easily find that the error from neglecting the influence of moment of inertia of mass in a vertical short beam is less than that from neglecting the influence of shear stresses. If the moment of inertia of mass is not considered a more direct development of the equations may be made.

Equation (7) may be derived from Equation (1), and from the well known elastic equation: which is,

$$E\,I\,\frac{\partial^4 y}{\partial x^4} = -\frac{\partial V}{\partial x} \qquad (54)$$

---

[28] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

Likewise, Equation (26) may be developed from Equation (1) and from the elastic equation:

$$E I \frac{\partial^4 y}{\partial x^4} = - \frac{\partial V}{\partial x} + P \frac{\partial^2 y}{\partial x^2} \quad \text{. . . . .} \quad (55)$$

Henry D. Dewell,[29] M. Am. Soc. C. E. (by letter).—This paper is an excellent and terse presentation of those fundamentals of the behavior of earthquakes, and of structures during earthquakes that are of particular importance to the structural engineer. In Section I, Mr. Galloway has quite properly emphasized the complexity of the earthquake and of the problem of giving a structure earthquake resistance.

The writer believes that the statement (see heading: "Earthquakes and Their Effects: Relation to Structures"), "In the case of high, narrow structures the vibration period is often close to that of some of the maximum waves and, unless the structure is well designed, serious damage will result if the shock is of long duration," should be amplified. The danger of resonance is not confined to high and narrow structures; neither is it at all certain that only the maximum earthquake waves are dangerous to structures. Herein it is understood that by the term "maximum earthquake waves" is meant the transverse waves that have the greater amplitudes. If the periods of the earthquake and the building are substantially in agreement, serious damage will undoubtedly occur, even if the shock is of short duration; consequently even a "well designed" structure will probably suffer seriously. After all, the term "well designed," when used in connection with ability to resist an earthquake, is rather relative. The writer understands that, as used, it means a construction with the structural units well arranged, designed for ample dead loads and live loads, with conservative unit stresses, with walls built integral with the structural frame or well tied and anchored thereto, and with all connections of sufficient capacity to develop the full strength of the members connected; and, in addition, it means that the structure has been designed to resist a definite lateral force from any direction.

Mr. Galloway has correctly stated (see heading "Earthquakes and Their Effects") that, "The foundation material is the important element of the movement [of the ground in an earthquake]. Solid rock moves the least; deep alluvial soils saturated with water * * * will have the greatest movement." Lest inference be drawn from this statement that damage is always greater when the structures are founded in alluvial soils than in harder or diluvial soils, it may be mentioned that in the 1923 Tokyo earthquake the damage to brick and concrete buildings was greater to those buildings situated on the up-town diluvial soil than to similar buildings situated in the down-town soft alluvial soil.[30] R. R. Martel, M. Am. Soc. C. E., states[31] that:

> "* * * somewhat similar results were obtained from a study of effects of the Long Beach earthquake of 1933. There the damage to brick build-

[31] "Effect on Foundation of Earthquake Motion," by R. R. Martel; presented at the meeting of the Soil Mechanics and Foundations Division, San Francisco, Calif., July 26, 1939 (not published).

> ings located on the softer, more recently deposited alluvium with ground water from 2 to 10 ft. from the surface, was less than to similar buildings on the older, more firmly consolidated marine terrace deposits with ground water not so close to the surface."

Referring to the relative accelerations in soft and hard grounds, he aptly states, "for one earthquake the flip of a coin will furnish as satisfactory a guide as any in forecasting the relative accelerations on different materials." The foregoing statements are illustrations of the often observed phenomenon, that almost every rule or law of earthquake action on structures has some exceptions which are apparently inexplicable.

Referring to the possibility of resonance, Professor Hoskins states (heading "Conclusions from General Theory of Forced and Free Oscillations") that to prevent this

> "* * * it would be necessary to have full knowledge * * * regarding free-oscillation frequencies of actual buildings * * *.
>
> "As regards the second question, it is obvious that the designer is powerless to avoid the dangerous condition unless he is able to estimate in advance the natural oscillation frequency of any projected building. Of great value for this purpose would be data concerning actual oscillation periods of many existing structures so selected as to serve as types."

In this connection Mr. Galloway has noted (heading: "Earthquakes and Their Effects") that "The Earthquake Committee filed with its report[3] the vibration periods of a number of buildings in San Francisco * * *. Other data of similar kind have been published." It may be well to amplify Mr. Galloway's statement by noting that from this rather small beginning of the Earthquake Committee resulted the extensive program of measurements of periods of buildings, bridge piers, water tanks, and dams, by the U. S. Coast and Geodetic Survey, the results of which have been published in the *Bulletins* of the Seismological Society of America and are summarized in the Survey's *Special Publication No. 201*, "Earthquake Investigations in California, 1934–1935." In all, the Survey made about 1 200 observations on 400 buildings, 150 observations on 41 tanks, 200 observations on special structures, and 500 ground observations. A portable ground and building shaker was developed at Stanford University, Stanford University, Calif., and tests were made with this machine on buildings, dams, and bridges, and on the foundation ground itself.

Because of the complexity, intricacy, and the length of mathematical work necessary for the solution of the stresses in any but the most elementary forms of structures when subjected to even simplified types of vibratory motion, the writer believes that the greatest gain in current knowledge of earthquake-resistant design will come from experimental studies of models of buildings and other engineering structures subjected to artificial vibration of predetermined pattern, amplified by theoretical study. The most promising procedure is the determination, if possible, of those static loads which may be used as the equivalent of the dynamic earthquake shears for buildings of different shapes, heights, and mass distribution. Valuable work in this field has already been done by Prof. Lydik S. Jacobsen in the Vibration Research Laboratory at Stanford University, Professor Martel at the California Institute of Technology, at Pasadena, Calif., and Prof. Arthur C. Ruge at the Massachusetts Institute of Technology, at Cambridge, Mass. Some of the results of their work have been published from time to time in the technical press. Of particular interest are the experiments[32] of Professor Jacobsen on a model of a 16-story and a 29-story building.

A special type of structure studied by the writer, acting as a member of Mr. Galloway's Earthquake Committee,[33] was the tall, free-standing chimney. Sufficient data were available, through the courtesy of the Japanese members of the Committee, on the behavior of a large number of these chimneys during the Tokyo earthquake of September 1923, to warrant a study. The writer endeavored to correlate the location of the fractures in these chimneys with the theoretical locations when computed according to the impact theory presented by Professor Le Conte[27] in 1926 using assumed ground accelerations thought to be reasonable. Conversely, he computed the ground accelerations theoretically necessary to cause the fractures that had occurred. In these computations the formulas developed by Professor Le Conte were modified with the assistance of Walter Ruppel, Assoc. M. Am. Soc. C. E., to adapt them to the case of a tall, free-standing chimney, of truncated form, considered to act integrally with its foundation, the latter usually being a massive block of concrete. These modified formulas represent the so-called "hammer theory."[3]

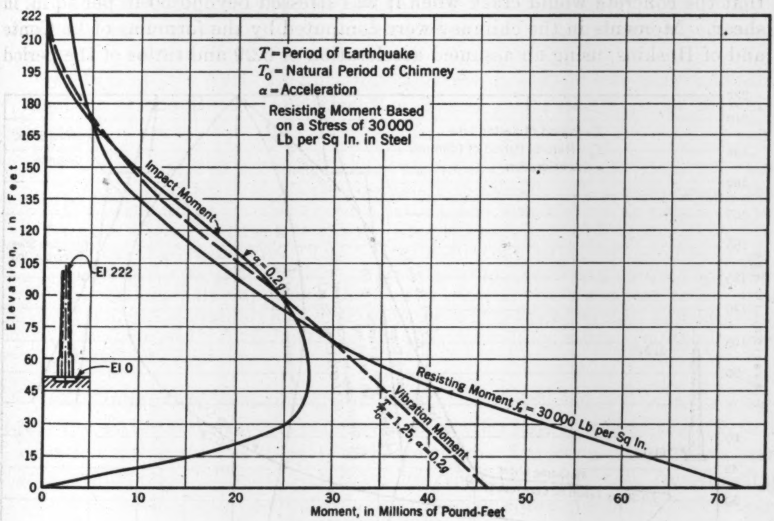

FIG. 9.—MOMENT CURVES

---

[32] "Experimentally Determined Dynamic Shears in a Sixteen-Story Model," by Lydik S. Jacobsen, and Robert S. Ayre, Jun. Am. Soc. C. E., *Bulletin*, Seismological Soc. of America, October, 1938.

[33] See *Civil Engineering*, March, 1932, p. 204.

The results of the investigation of the Japanese chimneys were neither consistent nor reasonable and the writer came to the conclusion that the action of these chimneys had not been similar to that of a free, prismatic rod subjected to a single force.

It may be questioned whether there is any earthquake phenomenon corresponding to a sudden blow or an impulsive force. It has been ascribed by some to the first longitudinal waves of the earthquake as distinguished from the large transverse waves which result in the violent swinging of structures. Seismographic records, however, have not generally indicated any such violent longitudinal waves. Possibly the sudden transition from the preliminary vibration of the earthquake wave to the first violent swing of its major portion might produce, in effect, a sudden blow.

A few years ago the writer's office had occasion to investigate the earthquake resistance of a free-standing, reinforced concrete chimney, 222 ft high. The theoretical resisting moment of the chimney was computed assuming that it would fail when the stress in the reinforcing steel reached 30 000 lb per sq in. In like manner, the shearing resistance of the chimney was computed assuming that the concrete would crack when it was stressed beyond 50 lb per sq in. in shear. Moments in the chimney were computed by the formulas of Le Conte and of Hoskins, using an assumed acceleration of 0.29 and ratios of the period of the earthquake to the natural period of the chimney of 1.25 and 1.50. The curves representing the results of these computations are shown in Figs. 9 and 10. Referring to Fig. 9, the moment curves, it will be seen that the zone in which the active moments exceed the resisting moment is essentially the same

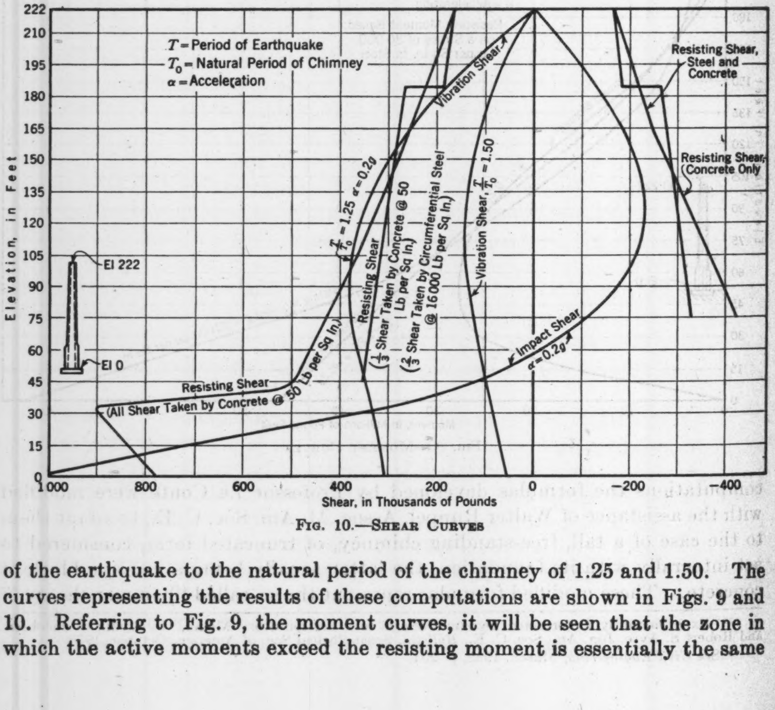

FIG. 10.—SHEAR CURVES

for both the impact moment and the vibration moment. It is true that the excess amount of earthquake moment over the resisting moment is greater for the impact moment curve than for the vibration moment curve, although a not greatly different assumption of earthquake period and acceleration would have produced a larger earthquake moment. For example, a ratio of periods $\frac{T}{T_0}$ of 1.00 instead of 1.25 would throw the vibration moment curve farther beyond the curve of resisting moment. It is also to be observed from Fig. 10, showing the shear curves, that the theoretical zone of over stress is essentially the same as that determined by the moment curves, although the over stress of shear is very much less than that of moment.

For many years engineers generally accepted the stated conclusion of the Japanese seismologist, the late F. Omori, that free-standing chimneys usually broke at two-thirds their height, and that their action during an earthquake somehow brought into play their centers of percussion, although the center of percussion of a chimney of the usual truncated form is nearer one-half its height than two-thirds. Indeed, the term "center of percussion" came to be associated with tall, free-standing chimneys and it was even thought by some that the value of acceleration should be doubled when used in the design of chimneys to provide for the effect of impulse.

In 1929 at the World Engineering Congress, I. Hiroi,[34] late Superintending Engineer of the Home Department of Tokyo, presented a paper in which he stated:

> "Of over 240 chimneys taller than 50 ft * * * more than 110 were totally wrecked, and over 40 seriously damaged. It is remarkable that the point at which the rupture took place was almost anywhere in the whole height, contrary to the old idea that it should be at two-thirds the height in tall chimneys. The determination of the dimensions of a chimney sufficient to resist the actions of great earthquakes is not simple; but when proportioned by supposing the acceleration at the lower end to be equal to that of the ground, (say 3 000 m.m. per second per second), and assuming it to increase by 50% nearer to the top, it would be strong enough in most cases."

Concluding this discussion of chimneys, the writer believes it more probable that the earthquake fracture of free-standing chimneys is due to the effects of vibration rather than of impact, and results from failure in moment or shear, or a combination of both. It must be recognized that tall, free-standing chimneys, both of brick and of reinforced concrete, are special types of structures that are inherently vulnerable to earthquakes.

JOHN D. GALLOWAY,[35] M. AM. SOC. C. E., AND LYDIK S. JACOBSEN,[36] ESQ. (by letter).—Some points made by the several writers who have discussed this paper seem to require further explanation in order to make the subjects more clear.

[34] "Prevention of Damage to Engineering Structures Caused by Great Earthquakes," by I. Hiroi, Paper No. 117, *Proceedings*, World Eng. Cong., Tokyo, 1920, Vol. 9, p. 25.

[35] Cons. Engr., San Francisco, Calif.

[36] Prof. of Mechanical Eng., Stanford Univ., Stanford University, Calif. [Prior to his death on September 8, 1937, Professor Hoskins had persuaded Professor Jacobsen to act for him in preparing the closing comments of this paper. Throughout, the word "writers" is interpreted to mean Messrs. Hoskins and Galloway, with the understanding that, in the closing discussion, Professor Jacobsen is interpreting his knowledge of Professor Hoskins' views.]

Mr. Hadley seems to doubt the value of the theoretical treatment of design of structures to resist earthquake waves, owing to the great complexity of the forces. The value of the theoretical treatment lies in the fact that, if the treatment is correct, there will result a consistent design of the structure. The assumptions are necessarily uncertain and should be simple. However, when once made, there is a possibility that the design will be so consistent that no part of the structure will be found wanting when subjected to forces of the shock. It is to be doubted whether Mr. Hadley would advocate designing a structure where "good guesses" formed the basis of design. Under such a procedure, some brace or other essential member might be left out, and the whole structure brought to failure thereby. Experience, such as that indicated by the writers, is a guide in making the assumptions upon which theory is based, such as the acceleration expressed as a percentage of gravity, which is of the greatest value. Once this is determined, theory may be brought in to produce a fairly consistent design. The writers must differ from Mr. Hadley in his statement that "* * * it is not apparent that the weight of the construction has any appreciable bearing on the matter at issue." The mass of the structure measures the forces set up therein by the earthquake. Reduction of mass, with the corresponding decrease in stresses, permits a design in which such stresses can be taken care of in a better manner. This remark applies particularly to the joints of an articulated structure. In regard to visible surface waves in earthquakes, it is suggested that Mr. Hadley examine reports of various earthquakes where such waves have been reported. Possibly the experience of one excited observer in Tokyo and a quotation from Shakespeare would not be considered sufficient to offset the uniform testimony of the existence of such waves.

The comments by Mr. Beanfield constitute an interesting summary of the problem from his point of view. The writers are in agreement with most of his remarks, but they cannot concur with his positive statement in Item (6) that "It is a well-established fact that the only proper method of judging earthquake intensity is by the kinetic energy method." It is true that much is in favor of this method, and that rationally it has a good foundation, but it has not yet become "a well established fact." It remains an hypothetical, although a plausible, method.

Suggestion (*a*) offered by Mr. Beanfield is a rule for computing the "maximum period, acceleration, and dynamical shears," presumably on the criterion of maximum fundamental mode deflection within the elastic limits of the materials. However, the statement that "the maximum statical deflection * * * [due to 0.1 g] is also approximately the maximum amplitude of its transient vibrations" seems to be without theoretical backing; at least the reference given to Timoshenko's book[11] does not warrant such sweeping conclusions. Again, under Suggestion (*c*) the statement that "The natural period of a structure ascertained by the foregoing method should not exceed 0.5 sec" is blunt and arbitrary.

The writers agree with Mr. Chew in advocating that empirical formulas for fundamental periods of buildings be used whenever sufficient observational data are available for existing buildings in the vicinity.

The influence of the non-rigid ground on the periods of a structure is largely a matter of guess work even if, as Mr. Creskoff suggests, dominant periods of the site had been obtained before the building was erected. For this reason, it is questionable what is meant by "reasonable accuracy" in the determination of the period of a projected structure. The usefulness of Table 2, given by Mr. Creskoff, would depend on the designer's ability to estimate the period ratios $\frac{T_b}{T_g}$, and even then the use of Mr. Creskoff's table is extremely arbitrary.

The discussion by Professor Ruge mentions the fact that a closer "tuning in" of earthquake frequency with structural frequency is necessary for the higher modes of vibration if equal dynamic magnification is to be expected. The writers agree with this fact and admit that the absolutely "steady state" of vibration, considered in the paper, is so idealized that application to actual conditions must be tempered with considerable insight and experience on the part of the designer. Professor Ruge also calls attention to the fact that a large building will interact with, and influence, the ground on which it stands to such an extent that the forces of the moving ground are not unlimited. This is also in agreement with the view of the writers; moreover, this interactive play of a large building with its foundation makes the period ratio $\frac{T_b}{T_g}$, used by Mr. Creskoff as well as by the writers, rather indeterminate.

Mr. Huber differs from the analysis of the writers which holds only for the "steady state" and in his investigations of the Seal Beach Power Station chimney he used the "impact theory" as developed by Professor Le Conte. It will be recalled that the "impact theory" is based upon the supposition of infinite rigidity of a perfectly free rod—that is, a rod without elastic distortions and consequently without vibrational properties. One must admit that actual structures fall short of approximating these assumptions. In the case of the Seal Beach chimney there was an agreement between the observed damage and the results of the theory. However, the location of the damage is equally well explained by the elasto-dynamic theory if it is supposed that the second mode vibration was excited instead of the fundamental mode. Calculations and observations make it seem highly probable that the earthquake of March 10, 1933, excited the second mode of the chimney much more violently than the fundamental.

The analysis of this particular chimney indicates the difficulties that confront an engineer when called upon to determine what caused the damage to the structure during the earthquake. Here was the case of a very high and heavy chimney held aloft upon a steel frame—a very unusual design, but one not entirely unknown. Mr. Huber adopted an analysis based upon a certain theory and the observed effects of the earthquake seemed to correspond thereto. Another theory probably would have reached substantially the same result and also might have justified the recommendation made by the engineer that the chimney be reduced in height. No mistake was made in so doing, but the writers are of the opinion that the weight of evidence favors the elastodynamic theory.

In this connection attention may be called to the fact that the speed of the earthquake waves is such that when any structure is encountered, the effect would be similar to a blow or sudden impact. The waves move at a speed of several miles per second and it is a well-known fact, as in bridges, the suddenness of the blow such as from a moving train is of material effect in increasing the stresses in the structure. In modern bridge design, impact stresses play a material part in the design. The entire discussion indicates the complexity of the subject and demonstrates how differences of opinion may arise.

The writers agree with Mr. Dewell's suggestion, namely, to amplify the statement under the heading "Earthquakes and Their Effects: Relation to Structures." The analysis given by Mr. Dewell, of a 220-ft chimney, is also very interesting. Again, the moments and shears due to the existence of higher mode vibrations will explain Mr. Dewell's quoted statement, due to I. Hiroi of Tokyo, that the damage to a chimney might be located "almost anywhere in the whole height."[34] The writers concur with Mr. Dewell in believing it more probable that earthquake fractures of free-standing chimneys are due to the effects of vibration rather than of impact.

The substance of the writers' paper lies in the statements of the complexity of the problem and the necessity for some simple assumptions that would make the problem one in which a consistent mathematical treatment was possible. There does not seem to be any material differences among those who have discussed the paper, as to the treatment adopted. It may be assumed that there is a general approval of the assumptions made by the writers. It is not contended that the treatment represents the last word on the subject, but rather the reverse is true. As more data are accumulated upon the subjects of earthquakes—especially as to the duration of the movement, the acceleration, the characteristics of the waves and (which is important) the similarity to assumptions that are within the range of mathematical treatment—a revised treatment may be possible that will accord with the additional knowledge acquired.

TRAFFIC PROBLEMS IN METROPOLITAN AREAS

By Earl J. Reeder,[1] M. Am. Soc. C. E.

With Discussion by Messrs. George H. Herrold, Thomas Buckley, D. Grant Mickle, Robert A. Mitchell, Cleveland B. Coe, and Earl J. Reeder.

Synopsis

The purpose of street traffic is to convey persons from where they are to where they want to be, and goods from where they are to where they are wanted. Time is an important factor because delays defeat this purpose in part. Safety is an even more important factor because accidents defeat the purpose entirely.

In general, the traffic problems before all municipalities to-day relate to safeguarding the purpose of traffic by reducing the probability of congestion and accidents and by helping traffic to move expeditiously and safely. In metropolitan areas these problems are generally more serious than in smaller communities because the concentration of traffic is greater. Although these problems may be variously classified, they will be treated herein under six headings, some of which overlap to some degree. These headings are: (1) Helping traffic through danger spots; (2) protecting the person on foot; (3) stopping the increase in night accidents; (4) reducing traffic concentration; (5) keeping speeds safe for conditions; and (6) providing for loading and parking.

Helping Traffic Through Danger Spots

Contrary to the belief of many, a city street is not a continuous scene of human and mechanical disaster. In fact, traffic runs along quite well at most places, thanks to the judgment and skill of the majority of drivers and pedestrians. At certain points, however, accidents and congestion problems tend to recur because the difficulties are more serious than individuals can cope with successfully.

In general, a higher concentration of accidents occurs in the more congested districts, although the severity is greater in areas with less congestion. Little

Note.—This paper was presented at the meeting of the Highway Division, New York, N. Y., January 20, 1938, and published in December, 1938, *Proceedings*.

[1] Chf. Traffic Engr., National Safety Council, Inc., Chicago, Ill.

trouble is encountered where the movements are simple and clearly evident to drivers and pedestrians. Where the movements are complex and confusing, drivers and pedestrians do not fully understand the situations before them and do not have time to analyze these problems for themselves.

Proper accident records are imperative for determining where these "sore spots" are, and for deciding upon measures which will solve the problems as they exist. There is no better single indication of what is wrong with traffic than the accidents that occur in it. In fact, there is no indication that equals the accident records in importance. Traffic volumes are important in the solution of traffic problems, but they do not show where the conflicts are. Speed observations are helpful but, likewise, they do not show where traffic gets into difficulties. The accident records show where, when, and how these conflicts occur. Any community which does not have good accident records should provide for their proper accumulation as the first step in attacking the traffic problem.

One important problem of metropolitan areas (important there because traffic is denser than in smaller municipalities) is to simplify traffic at the "sore spots" and to provide assistance for vehicles and pedestrians to move safely. The purpose of the signs, signals, and markings which are installed for traffic control is to give the individual driver or pedestrian a little greater assurance that others are going to move in a certain way at a certain time so that he may act accordingly. For example, a "stop" sign at an intersection is intended to bring traffic from one direction to a full stop so that the drivers in that direction will work their way into the traffic on the cross street at moderate speeds after finding out that the way is clear.

One of the important principles in traffic control is to provide enough restriction or assistance, but no more than is necessary for safe and expeditious movement of traffic, because, after all, human beings do desire to be safe and will act in accordance when they know what to do. Acting on this principle, the time is passing when a "stop" sign, a "stop-and-go" signal, or some other favorite measure is expected to prevent all kinds of accidents and eliminate congestion from any cause. Studies of accidents before and after the application of these various measures have shown that unreasonable regulations—restrictions which are not adapted to the accident experience pattern, for example—do not accomplish results. There is a direct relation between stop-sign obedience and the reduction in speed that is necessary for safety, determined in terms of locations, of view obstructions on corners, street widths, and other definable factors. As a result of these studies, the stated speed "slow" sign which reads, "Slow to 11 Miles," "Slow to 14 Miles," or slow to any other speed which is computed as the critical speed, has been developed for use where full stops are not necessary for safety, but some restriction of speed is needed. This sign slows down the driver to the speed at which he can determine what the other drivers are doing and can act accordingly.

The development in "stop-and-go" signals and in their use is another good example of the simplification of traffic movement to avoid conflicts. Studies made in a number of cities in 1930–31 showed that such signals are not panaceas for all traffic ills but are invaluable for the types of problems that they can solve. Gradually, their adaptation to complicated places has been expanded. More phases of the cycle of colors have been added for complicated situations. Pedestrian "walk" lights have been developed. Special "turn" arrows have been added for unusual movements. Traffic and pedestrian actuation has been developed for fitting the operation more nearly to the traffic demand.

In metropolitan areas the demands upon traffic control reach their highest degree of concentration. It is there that greatest complications of traffic occur; and it is there also that the efficient use of the streets at the same time that the greatest of safety is provided, is imperative. For that reason extensive inter-connected signal systems have become necessary to enable vehicles to move with uniformity and continuity and, at the same time, to provide protection for pedestrians. Although such systems must often be complicated as to design, they must be simple so far as their appearance to the public is concerned because their purpose is to simplify traffic movement and make it easier for each driver and pedestrian to understand what he is supposed to do at each point.

No signal installation meets this condition more fully than the type in use on Michigan Avenue, in Chicago, Ill. The timing is extremely complicated because, at points, traffic is controlled independently for opposite sides of the street. However, every effort has been made to make clear, to drivers and pedestrians, how they are supposed to use the signals. Turning signals show when certain turns may be made to avoid conflict with other movements. Pedestrian signals show when pedestrians may cross. Traffic is kept in step by flashing the part of the green light that is not normally required for handling the volume of traffic at the less important intersections.

To simplify traffic by signs, signals, and markings, the engineer must do some more or less complicated planning in order to determine what should be done at certain locations and he must give the public the advantage of this solution by unmistakable means. Careful engineering planning is thus substituted for snap driver judgment, to a large extent. Traffic control systems of the future will probably be considerably more complicated in design than those of the present, although traffic movement will be greatly simplified thereby. As public understanding increases through traffic safety propaganda, public acceptance of such aids will be greater, and the results will be even more successful than those that are now being experienced from such measures.

PROTECTING THE PERSON ON FOOT

The pedestrian problem is one of increasing seriousness. The greater the speed and mobility of the vehicle, the more difficult it is for the pedestrian to foresee the hazards that surround him. The freedom of pedestrian action of former days must be restricted as the differential between vehicle speeds and pedestrian speeds increases. This is particularly true in congested areas where there are more pedestrians as well as more vehicles.

The pedestrian problem is particularly serious among persons who have never driven automobiles and who do not appreciate the limitations upon vehicle performance. Perhaps this fact is best shown by data from Connecticut for a recent period of five years during which 1 231 pedestrians were killed. Of these, 83% were of sufficient age to be eligible for drivers' licenses, but only 5% were licensed operators. This emphasizes more effectively than almost any other available data the importance of public education, as well as actual control measures, for preventing accidents.

In the past, too little attention has been devoted to the pedestrian, in devising control measures. Too little emphasis has been placed upon the need for educating the pedestrian concerning the hazards of traffic. Propaganda has been directed at the driver and control measures have accrued to his benefit; but the pedestrian has been considered a free agent who can protect himself if he is sufficiently concerned.

There are, and will continue to be, many "stop-and-go" signals without special lights for the pedestrian; and he must be brought to closer conformance with the usual signal indications. To encourage this co-operation the cycle of operation of signals should not be longer than is necessary to handle the traffic efficiently because pedestrians will not wait when there is no traffic moving.

The pedestrian education program must often be selective. In a recent traffic survey of Vancouver,[2] B. C., Canada, it was found that the residences of many of the pedestrians, as well as of many of the drivers, who were involved in accidents, were in areas of special racial, language, or social characteristics which would not commonly be reached by the ordinary means of public propaganda. Many of them lived in the Oriental sections, for example. The usual clubs, English language newspapers, and similar agencies did not reach those people, and their lack of appreciation of the traffic problem made many of them unsafe drivers and unsafe pedestrians. The public must be educated concerning traffic problems through agencies that they understand and in which they have confidence.

STOPPING THE INCREASE IN NIGHT ACCIDENTS

Closely related to this problem of pedestrian protection is that of the increasing seriousness of night accidents. Pedestrians, in particular, are susceptible to accidents at night because they carry no lights, and dark clothing often gives little or no reflection of vehicle lights. For their protection proper street lighting is a necessity. Experiences in Detroit, Mich., Evanston, Ill., and other localities have shown that good lighting does reduce certain kinds of night accidents, particularly those involving pedestrians.

How far the engineer can hope to go in providing lights for rural highways may be a problem involving some controversy, but concerning the proper lighting of city streets where vehicles and pedestrians must intermingle—and street intersections are frequent—there can be no question. It is there that the problems of night accidents are more highly concentrated. It is there that headlights often are of least value in providing adequate visibility.

Adequate lighting is more than a question merely of increasing the candle power of the luminaries. It involves proper spacing, mounting height, position with respect to the street, and types of luminaries. It is more than mounting a light on top of a post to show approximately where the street is. It is a matter of providing illumination to reveal objects that would otherwise be hidden from the view of drivers at night.

---

[2] "Improving Street Traffic, Vancouver, B. C.," by the National Safety Council, 1936–38.

Here, again, the best indication of what is wrong is the accident records. In the traffic survey of Honolulu, Hawaii, in 1936, a spot map of night accidents was prepared and it was found that the spots were particularly dense at certain points and along certain streets, and that they were very few at other places. In general, the density of the spots seemed to bear an inverse relation to the quantity of the lighting, much of which was very defective. Obviously, the proper approach was to improve the lighting first where the ratio of night accidents to day accidents was the greatest. That is a fair approach for any city to make to its street-lighting problem.

The night-accident problem is not to be attacked entirely from the standpoint of general lighting although that is an important part. Special hazards must be specially lighted. Many persons have been killed or injured in vehicle collisions within improperly lighted safety zones, for example. Center-posts in railway underpasses have taken their toll. Signs that were not visible at night have failed to prevent those accidents which they prevented in the day time. The traffic problems at night are entirely different from daylight problems because the very source of illumination is different. Special illumination is required at hazardous places to make sure that the hazards can be seen, and that the way to avoid them is apparent.

REDUCING TRAFFIC CONCENTRATION

One of the fallacies that must be exposed and overcome is the feeling that is often held by merchants and business people that traffic density is a good sign of business prosperity. It may, rather, be a sign of impending business decay and decentralization. An important problem is to differentiate between potential business traffic and through traffic that has no commercial significance. In some cities as much as 30% of the traffic in central business districts passes through without making any business stops. Means should be provided for traffic that is not potentially commercial to by-pass congested districts so that these areas may be reserved for easier access by drivers and pedestrians who go there expressly for business purposes.

This is to be done by providing convenient routes properly marked and safeguarded. It is not to be done by compulsion. Traffic that is not potential business can be directed easily over any convenient route that is properly marked and is a more comfortable route to travel than the streets through the central business district.

Too many cities are trying simultaneously to maintain convenient access to the business houses for business purposes and to handle considerable through traffic which can do nothing but make it more difficult for potential customers and clients to patronize the business places. Persons who are not potential buyers prefer to use routes that do not have the confusion, congestion, and delays of business streets. However, traffic tends to go toward business districts if alternate routes are not properly marked because it is in such districts that drivers can get their direction to their destination most conveniently; and the business districts are usually plainly seen from almost any part of the city. It is only through proper routing that the necessary segregation of business and non-business traffic can be made.

KEEPING SPEEDS SAFE FOR CONDITIONS

One of the big problems of municipalities is to adapt traffic speeds to conditions. The day of installing speed-limit signs at the boundaries of municipalities and leaving the individual driver to determine whether he is driving safely as long as he keeps within these speeds, is passing rapidly. The obligation of speed regulation for safety is not discharged that easily. Particularly on densely-traveled arterial routes, the problem of directing the traffic means moving it as rapidly as the physical conditions and safeguards will permit in safety. It is not always possible for the driver to judge accurately the maximum safe speed from place to place because hazards are sometimes hidden. Speed zoning, in which the maximum permissible speeds are determined by engineering investigation and are posted conspicuously, is an important new development. It is almost as necessary as route-marking for directing traffic conveniently and expeditiously, with safety.

One of the most important traffic problems is to create an adequate public understanding of the meaning of speed zoning, so that drivers will observe the restrictions that are imposed. They are likely to look upon any speed limit as a remnant of former days when the many who had no automobiles did not hesitate to impose extreme restrictions upon the few who did have them. Traffic administrators must show these drivers that the purpose of a speed-zoning sign is to give every driver the advantage of the detailed engineering investigation, which may have taken days or weeks in order to determine the critical speed so that he may not have to depend upon his momentary judgment in an emergency to determine how fast he can go.

In "stop-and-go" signal systems, proper inter-connection and timing are very effective in speed control. Progressive signal systems are planned to allow vehicles to pass through in platoons at pre-determined speeds. If they go at appreciably higher or lower speeds, they come to red lights and are stopped. Such designs are controlled by the volume of traffic that must be handled, the block lengths, and the cross-traffic at the different intersections. There probably is no more intriguing problem in traffic engineering than the design of a flexible progressive control system for a street with varying block lengths and dense traffic. Regardless of their actual complications, their indications to the public must be simple, direct, and unmistakable, as well as reasonable.

Speeds must be appropriate for street conditions. Where drivers are unable to recognize, quickly, the practical limitations on their speed, restrictions must be applied. As in traffic control for all other purposes, these restrictions must be reasonable and they must be adequately "sold" to the public. Most drivers will comply with such restrictions when they are understood, but some must be required to do so by enforcement.

PROVIDING FOR LOADING AND PARKING

Parking is a problem involving much controversy in congested business districts. It is probably one of the most misunderstood problems in the entire field of traffic administration. There are those who want unlimited parking and those who want to eliminate it altogether, depending upon their respective interests in the problem.

The primary purpose of parking, of course, is to provide access to business houses in business districts. It is a problem which usually develops simultaneously with other problems. The denser the traffic, the more acute is the parking demand likely to be and the more serious is the conflict.

The primary purpose of providing for access to the curb is to receive or discharge passengers or merchandise. When this has been provided to the full extent that is required, the remaining free curb space may be used for parking. However, the process has often been reversed—the curb has been parked full of cars in actual storage for various lengths of time, and so the driver, in order merely to load or unload, has been forced to take any place he could find to stand his vehicle for a few minutes. It may have been opposite a fire hydrant or a safety zone, or double-parked in the street, if no place at the curb was available.

It is inconceivable that cars will continue to be permitted to park almost bumper to bumper in busy city streets, making it difficult for vehicles to load or unload at the curb. More off-street parking and loading spaces must be provided. The time will soon come when restrictions will require all business buildings to have off-street provisions for parking and places within them, or on adjacent property, for the loading or unloading of merchandise, leaving the near-by streets free for stops to load or unload passengers.

Until that day cities must resort to time restrictions upon parking which will insure a sufficiently rapid turnover in the use of curb space to give every one a chance and to provide for convenient loading and unloading. A new development in the supervision of parking regulations is the parking meter which shows, mechanically, the length of time that has elapsed since a coin was inserted by the driver who parked there and reveals at once the expiration of that time and the act of over-parking. Meters do not solve the parking problem, but they do help the police materially in supervising and enforcing the restrictions that exist.

MASS TRANSPORTATION

In dealing with these problems of traffic one must not overlook mass transportation. In the street space used per person carried, the private passenger vehicle is much less efficient than the bus or street car. In the placing of street car and bus stops, in the establishment of routes, and even in the restriction of traffic, buses and street cars should be impeded the least that is consistent with safe and expeditious movement of all traffic.

Many of the measures that have been mentioned apply as well to mass transportation as to private passenger vehicles. Others must be adapted. The timing of "stop-and-go" signals applies to both. The establishment of bus stops requires the special clearing of parked vehicles so that the stops may be made at the curb in the most convenient place for all concerned. Like all other problems in traffic regulation and control, those pertaining to mass transportation must be solved on the basis of the conditions that exist. Accident records must be consulted, traffic volumes must be considered, and the demand for service must be taken into account and properly evaluated.

CONCLUSION

Traffic planning is distinctly an engineering function. The day is long past when trial-and-error methods are appropriate for solving the traffic problem. In former days traffic officials had to learn from experience by trying something and, if it did not work, trying something else. From that experience they have learned many things about the effectiveness of different measures for solving many kinds of problems.

Engineers still face the necessity for testing their planning efforts against actual results in accidents prevented, congestion reduced, and traffic expedited. Every measure that is applied should be preceded by the best analyses that can be made of the important facts about the problem to determine what is the most reasonable measure to be applied. It should be followed by equally thorough analyses of the results, to decide whether accidents have been prevented and, if so, what kinds. The engineer must determine whether traffic moves more freely and whether over-all time between destinations has been reduced. He must know whether he is handling more traffic or less, because it has been driven to some other streets. All these facts help him to guide his next steps in traffic planning, to apply appropriate corrective measures, and to anticipate the needs of traffic when he builds new streets or makes improvements.

Traffic planning provides the facilities for traffic movement. It provides the aids and safeguards that are needed. It attempts to determine what normal drivers and pedestrians do in traffic and to fit the facilities and regulations accordingly. Traffic planning must be reinforced by adequate education to inform the public about the use of the facilities that are provided. It must also be supported by adequate enforcement to require obedience from those who are wilful or negligent in their disobedience or misuse of the facilities. However, the responsibility of the engineer in traffic planning is to adapt his measures as nearly as he can to normal driver and pedestrian practices.

DISCUSSION

George H. Herrold,[3] M. Am. Soc. C. E. (by letter).—Observations and analysis of accident reports lead the writer to believe that the accident is most likely to occur where movements are simple and clearly evident to drivers and pedestrians, and that where the movements are complex and confusing, and drivers and pedestrians do not fully understand the situation, they proceed cautiously and safely. This would indicate that the cause of many accidents is in the driver. The careless driver does his damage where movements are simple and clearly defined. Careful drivers are becoming better drivers. They are constantly improving their technique, but the accident-prone driver presents a problem with which the careful driver cannot cope.

The writer has had an analysis made of several hundred accident records which were kept on forms presumably approved by the National Safety Council as filled out by police officers. They show where, when, and how the accident occurred; but it takes a keen analysis to determine the cause of an accident from these reports, because the "how" is not the "cause." In fact, it requires a trained investigator, of which there are very few. The report shows that "Vehicle No. 1, going north, collided with Vehicle No. 2, going west, at the intersection of 'X' Street and 'G' Avenue; (date), 10 A.M.; daylight; pavement dry; no defects; clear weather; drivers both males; not under influence of liquor; brakes O. K.; no car defects apparent: Driver No. 1 wore a brace on right foot; no signal or warning signs at the intersection; both drivers going straight through; and both had a license." The report shows where, when, and "how" the accident occurred (Driver No. 1 collided with Driver No. 2) but the cause of the accident can only be surmised. Probably both drivers were stubborn and would not "give an inch."

Accident reports are valuable; but the "vital point" (that is, human reactions at time of accident) is difficult to establish. An analysis of these reports by trained investigators is the real solution in helping traffic through danger spots. The railroads are correct in requiring a long course of training for a locomotive driver.

Records of "Stop Sign" violations and repeat violations by the same cars indicate that people refuse to stop where there is no vehicle in sight (see Table 1). The suggestion of another sign to take the place of the stop sign in many places, to read "slow to 10 miles" or slow to the computed critical speed is an excellent suggestion.

There is an unfortunate lag between increasing traffic congestion and the merchant's acknowledgment that he is losing business. Blight affects mercantile streets in many cities because of this lag. If the problem had been analyzed in the beginning a suitable by-pass could have been arranged and thus saved or delayed another blighted area. Proper routing through cities, and education as to the purpose of these routings, are among the essential necessities.

---

[3] Planning Engr., City Planning Board, St. Paul, Minn.

Every one knows that too high speeds are used by drivers in business districts. When a business man walks from his office to the bank he could save considerable time if he ran all the way; but he does not run. In fact, it has never occurred to him that he could save time by running. He walks in a dignified manner from one place to the other. The automobilist must also learn to move in a dignified manner when on congested business streets.

TABLE 1.—Observance of Stop Signs by 58 165 Drivers at Eleven Intersections in St. Paul, Minn.
(7:00 A.M. to 7:00 P.M.)

Description	(a) Came to Full Stop			(b) Shifted Gears but Did Not Stop			(c) Slowed but Did Not Stop			(d) Went Straight Through		
	1934	1935	1936	1934	1935	1936	1934	1935	1936	1934	1935	1936
Number of vehicles.......	24 827			25 764			5 249			2 325		
Percentage of vehicles.....	44.2	44.5	42.7	36.8	42.2	44.3	17.1	10.1	9	1.9	3.2	4

Providing for Loading and Parking.—The purpose of parking a car is to enable the driver to leave it, while attending to one errand or another. In most cities where an off-street parking space has been provided it is only about half in use; that is, twice the number of cars could probably be cared for in existing parking lots and garages when the people have been educated to make use of them. In St. Paul, Minn., the off-street storage capacity in the central business district is for 9 560 cars. The used capacity is 5 655 cars. In addition, parking space provided by utility companies and other private concerns, on their own grounds, for employees' cars, totals 1 630. Much the same situation occurs elsewhere. City officials have not yet decided whether it is a part of their business to provide parking spaces off the street, although a number are doing so on city-owned or tax-delinquent lands.

In St. Paul, with 90-min parking in the central business district, surveys developed 82% legal parking and 18% illegal parking, with 62% of all legal parking remaining at the curb less than 30 min. Based on these facts the parking ordinance was changed to provide 30-min and 60-min parking as more nearly in line with actual needs. In the 1937 survey it was found that 56% of the cars are legally parked and 44% illegally parked. The percentage of illegal parking increased, of course, with shortening of parking time and with the increased use of cars. The report of the National Association of Building Owners and Managers on parking meters, dated October, 1938, leaves no doubt that parking meters will cure this situation.

It is possible that the eventual solution of the parking and loading problem lies in condemning older buildings and land in the retail district, clearing the ground, and using it for parking of cars and "off-street loading," assessing the cost of such operation to the surrounding property owners. This would provide a free parking space with a limit of 1 or 2 hr to insure a logical turnover and a cash charge for any parking over-time. Such an area for off-street parking and loading should be planned to fit into the mosaic of the retail and office building district.

Mass Transportation.—An indication of the traffic picture of a city is the morning flow taking people to work. In 1924, 541 street cars brought into the St. Paul business district, in the morning, 31 000 passengers, whereas 9 250 automobiles brought in 14 677 passengers. In 1938, 419 street cars brought in 17 000 passengers; 71 buses, 763 passengers; and 18 100 autos and other vehicles, 29 100 passengers. In addition there were 7 200 pedestrians walking to work in 1938, a situation which was not considered important enough to check in 1924. Street space in St. Paul has been increased quite materially since 1924 but not in any ratio comparable to this increase in volume of traffic or use of street space—and this is true of many cities. Only by providing mass transportation that is more comfortable and attractive than a private automobile (such as the electric trolley bus) and limiting the use of private cars by those who do not need them downtown during the day (by enforcing drastic "no parking" regulations or parking meters, as is now proving successful in fifty cities) can this situation be altered for the better.

THOMAS BUCKLEY,[4] M. AM. SOC. C. E. (by letter).—A concise and interesting arrangement of traffic problems is presented in this paper. Sub-headings are neatly phrased and carefully chosen to include essential phases. They are in a form worthy of attention because they are adaptable to use outside the boundaries of purely technical review; and they lose none of their effectiveness if restricted solely to observation and discussion by engineers. Descriptive captions such as those in the paper prompt a reminder that the most urgent problem of the traffic administrator is to catch and hold public attention and to engender a respect for the profound importance of the personal factors in all traffic problems. After all, traffic control is outstanding among all technical fields as a procedure wherein the primary fundamental problem is to find effective ways and means of educating the public at large in human (and humane) behavior; or, in other words, to a full realization, and to the point of permanent, co-operative acceptance of their individual personal responsibilities as joint users and sharers of streets and highways. The extent of this problem is discernible in the following quotation:[5]

> "By what method can we make people realize that it isn't real fun to take chances with a motor car? What persuasions will be strong enough to convince the motorist that he should lose a minute and save a life? What means can be used to convince everybody that they should not drive after drinking?
>
> "How can taxpayers be persuaded that a drivers' training program in the high school is at least as important as a luxurious swimming pool? What kind of propaganda will it take to make drivers as courteous at the wheel as they are in the drawing room?"

Through the centuries the "human" characteristics of carelessness, thoughtlessness, heedlessness, selfishness, stubbornness, rudeness, and ruthlessness have become deeply imbedded in Man's nature. Unfortunately for his fellowmen, and particularly for traffic engineers, he elects to use streets and highways as places in which to display the mental perversities mentioned. Solution of the problems of self-control will never keep apace with the progress made in mechanical and design controls.

[5] See editorial: "Stop and Go," *Public Safety*, December, 1938.

The stressing of the time (speed) and safety factors by the author in his Synopsis suggests a second comment. This is that three utilitarian tests of a good highway should be emphasized more frequently as such. It is also a reminder that the third one of these tests seldom receives consideration commensurate with its importance in traffic problems. The three tests in mind are those of speed (time), safety, and comfort. The first two of these tests are under discussion publicly more or less continuously but the third (comfort) is seldom mentioned. This circumstance is probably due to the general acceptance of "comfort" as being covered by the "safety."

A well-designed highway is one that permits reasonable speed with minimum hazards and, in addition, assures maximum comfort to all its pedestrians and vehicular users—comfort not only in the sense of that "bodily ease," which is afforded by efficient design and construction, but including, as well, that comfort resulting from "mental ease," which can only be realized when travel upon public highways is guided and protected by effective controls. Mental dread or fear of highway hazards is particularly strong among young and aged pedestrians. It is not entirely absent in the minds of many automobile operators. Its presence under test may induce the fatal mental panic which so often contributes to the production of highway accidents. Tests for highway comfort must also take into consideration those lesser forms of highway friction, such as the crowdings, jostling, blocking, bumping, etc., constantly occurring during business hours on the sidewalks and in the roadways of the principal streets in main, wholesale, and retail centers of urban areas. Although the great majority of such happenings do not result in serious property or personal harm, they add materially to the mental stress and strain of daily life in large cities. These conditions are plainly evident at the crossings of countless highway intersections. The problem of comfort to pedestrian and rider at the junctions of main streets will never be completely solved; but, with such lessons in mind, new streets and highways should be designed and controlled, as far as it is economically possible, so that pedestrian and vehicular users may derive and share maximum enjoyment of them. To accomplish this end, highway discomfort must be reduced as much as controlling circumstances permit. A gospel of "friendly roads" with a mutual sharing of their privileges must be taught.

The author's consideration of the traffic situation in metropolitan areas is naturally concentrated on problems common to the urban or improved sections of such areas. Difficulties encountered in urban traffic problems are generally increased and their solutions made impossible of completion because of original planning defects or deficiencies. Owing to the nature of urban areas, controls such as signals, signs, markings, etc., with occasional islands, zones, channelizations, etc., constitute the common ultimate methods of solving the major group of traffic problems. These measures cannot entirely overcome the handicaps and hazards to traffic resulting from structural faults such as poor alignment, bad grades, lack of visibility, insufficient lighting, inadequate cross-section space, weak intersection layouts, etc. Few towns and cities are free of problems arising from such conditions. The lessons derived from traffic problems arising in urban sections of metropolitan areas should be applied advantageously not only in the planning and improving of new streets, but in replanning, wherever possible, all existing planned streets that are not developed as yet to a point which precludes corrections.

Metropolitan areas generally include, in addition to their built-up and partly built-upon sections, areas that are wholly unimproved. In some jurisdictions, these unimproved districts may actually include lands that are in two important stages of evolution: One class comprises planned sections (that is, areas laid out into streets and highways upon an official map or city plan, but not physically improved) and the second class embraces areas that are at present unplanned but are "ripening" rapidly for planning and development. What future traffic problems are hidden in such areas? Can proper precautions be taken so that these new sections will respond to a higher degree of traffic control with fewer problems than old urban areas? The municipal engineer and planner are deeply interested in these questions and from their viewpoint a discussion of traffic problems in metropolitan areas must also include the potential problems that may exist within already planned but unimproved sections, or which may happen by reason of incomplete future planning.

In his "Conclusion" the author rightly declares that "traffic planning is distinctly an engineering function." As such, it must acquire a vision which reaches out beyond the problems and necessities of traffic control installations on existing highways. It must begin with, and have a definite place in, the original planning. It must undertake to assure that areas already planned for unimproved districts are redesigned, if necessary, to meet reasonable traffic requirements and that they are adequately adapted for rational controls. The planner's objective should be to so plan or replan, and to so guide trends in development, that future traffic problems in the areas affected will approach an irreducible minimum in so far as damaging highway friction is concerned.

It is the responsibility of the engineer to develop and apply sound practice in the design and construction of streets and highways. To accomplish this objective, he has been meeting the requirements of speed, safety, and comfort for years by endeavoring to provide highways with dry foundations, solid and durable paving structures, safe grades, visible alignment, and even surface. To these qualities, he must now add that of traffic control, and co-operate with the planner to accomplish this end.

Modern highway use has produced new standards in the factors of volumes, intensities, loads, speeds, etc., which in turn have established new requirements with respect to the structural elements of highways—alignment, grades, cross-section design (including channelization), paving structures, curbing, drainage, fencing, railings, etc. All of these elements are directly connected with, and are an intimate part of, the problems of traffic control. Not only is sound engineering technique in design essential in minimizing traffic problems, but first-class construction and efficient maintenance are equally important. Worn-out or otherwise defective paving on certain streets and highways can disarrange the best of traffic controls completely and thus create a number of new local traffic problems. The design, construction, and maintenance of highways can be carried to any degree of efficiency required. Safeguards for traffic can be provided that will function to a high state of effectiveness. The difficulty encountered in building and equipping such highways is a very material one. Generally there are economic limitations to the extent to which such improvements are justified; and, in concluding this discussion, the writer raises another basic question in traffic control: "How can finances be obtained for furnishing, satisfactorily, the essentials—the means—necessary to complete the solutions of the many traffic problems after the ways of solving them have been fully determined? The problem of financing the solution of traffic problems deserves considerably more attention.

D. Grant Mickle,[6] Assoc. M. Am. Soc. C. E. (by letter).—In his excellent paper Mr. Reeder shows that city streets are not filled with human and mechanical disaster as is often thought. With the opportunities for conflict within the various traffic streams and eddies existing in metropolitan areas, it is indeed surprising that there are not more deaths and injuries than there are.

It is the problem of traffic engineers to schedule the movements of vehicles, persons, and merchandise, within the traffic stream, so that they are coordinated and made orderly and safe. Among the factors to be considered in such a program are the arrangement of the circulatory system, land usage, location and density of population, location of employment in offices, retail establishments and industries, and the location and usage of recreational and educational centers. The relation of these factors to one another, and their influence upon congestion and accidents, make up the traffic problem.

Because accidents constitute the spectacular phase of the traffic engineer's work, there has been, and still is, an insistent public demand that direct and positive action be taken to stop them. Mr. Reeder has presented many of the methods used in this direct approach. Automatic traffic-control signals, stop signs, speed control zones, and stated speed "slow" signs are among the control methods described. In connection with the latter device, it should be emphasized that it is difficult to enforce a sign reading "Slow to 11 Miles," inasmuch as the officer must pace the offender for a reasonable distance in order to obtain a conviction for an offense. Furthermore, care must be taken that a local ordinance provides authority for such a control device.

It is indeed true that the pedestrian problem is one of increasing seriousness. Many city officials, recognizing this problem, are providing legislation which places responsibility upon the pedestrian, as well as upon the motorist, in his activities in the traffic stream. No longer does the pedestrian have uncontested right to cross the street whenever and wherever he pleases. His actions and behavior are prescribed by law, and the designers of traffic-control signals are beginning to include indications in the signal to allot certain parts of the cycle to the pedestrian, restricting his movement during the remainder of the cycle.

---

[6] Traffic and Safety Engr., State Highway Dept., East Lansing, Mich.

One of the most prevalent locations for pedestrian fatalities is at the very outskirts of cities along the major highways. Sidewalks are often lacking at such places, highway lighting may be poor or non-existent, and the speed of vehicles is generally high. These factors combine to make the zone at the fringe of cities produce fatalities at a high rate.

In Michigan it was found in 1938 that, of all fatal pedestrian accidents on rural trunk-line highways, 34% occurred within the zone extending 1 mile out from the city limits. The rate per mile was found to be more than twice that of the second mile zone, decreasing gradually from that point as the distance from the city increased. This study focuses attention upon a pedestrian problem in which both the rural and urban officials must co-operate.

The genuine causes of accidents and congestion in metropolitan areas are usually of such a fundamental nature that their correction is costly. For example, in Detroit, Mich.,[7] it was found that the city's pattern of streets radiating from the central business district emphasized the conditions of congestion and hazard caused by the present-day use of the automobile in cities planned for other kinds of transportation. Studies of traffic volumes, and of the origin and destination of traffic, disclosed that these down-town streets carried not only vehicles bound for destinations within the district, but also thousands of other cars which passed through them to distant destinations because adequate cross-town arteries were lacking. Investigation of parking conditions, requirements, and habits indicated that desirably located off-street facilities were inadequate and that all of the legal, and much of the illegal, curb space was fully occupied. Not only were terminal facilities insufficient but the radial arterial streets were over-crowded for several miles away from the central business district.

The results of these unfavorable conditions upon business were revealed when comparisons of traffic counts over a period of twelve years showed that the number of people entering the district had actually declined although passenger car volumes had increased. Recommendations for dealing with these conditions included the construction of new cross-town arteries and the substitution of ample storage space in the areas occupied by deteriorated property surrounding the business district. In making these recommendations, the engineers went well beyond the act of merely counting and analyzing traffic movements. They took into consideration both the general physical plan and organization of the city, and the social and economic implications of real estate conditions in and about the central business district.

Too often officials and the public fail to realize the magnitude of the traffic problem or the losses attendant on congestion and accidents. The work of the traffic engineer, therefore, is often handicapped through lack of sufficient funds or proper interest in his plans. For example, a traffic report in Toledo, Ohio,[8] revealed that traffic accident losses amounted to $1 022 325 annually, as compared with annual fire losses of less than one-third of that sum, or $311 802; yet more than $2 was allotted to the fire department for each dollar of actual fire loss, whereas the traffic control and betterment services received only 34 cents for each dollar of traffic accident loss. Similarly in Louisville, Ky., whereas an average of 89 cents was spent to prevent one dollar's worth of fire loss, only 30 cents was spent to prevent an equal amount of traffic loss.

---

[7] "Street Traffic—Detroit," Michigan State Highway Dept., 1936–37.

[8] "Traffic Planning Report—Toledo, Ohio," Jensen, Bowen & Farrell, Engrs., 1937.

Parking or storage facilities in the business districts of cities are far from adequate; and providing these facilities is a problem of major importance. It is thought by some authorities that the provision of terminal facilities in the business district is a public duty, and if this is true, means for public ownership of parking facilities must be devised. Another view is that the primary use of the public streets is for moving traffic, and the parking of vehicles is a secondary consideration which should not interfere, to any appreciable degree, with the free movement of vehicular or pedestrian traffic.

Confusion is apparent in the attitude of the business men, who tend to demand strict regulation of all curb space, except that adjoining their own property. This conflict cannot be reconciled entirely; but it can be equalized by giving consideration to all the related factors, among which are traffic volume, vehicular speed, available space, the demand for spaces, and parking-time requirements.

The main function of time-limit parking regulations is to provide reasonable turnover and equable distribution of available curb space. Some cities are turning to parking meters as a means of enforcing time-limit regulations.

Business men realize that parking facilities are essential to business and that costly decentralization will result unless the problem is solved. Officials are attempting various means of improving off-street parking facilities or means of improving mass transportation facilities in an effort to curb decentralization tendencies.

A traffic survey in Youngstown, Ohio,[9] compared the number of persons accumulated in the business district by the use of mass transportation facilities with the number that used passenger automobiles. The average number of persons transported per mass carrier was 35.72, whereas the average per passenger automobile was 1.48. There can be no question of the relative efficiency of these two types of carriers in regard to economy in the use of street space. If the number of persons using mass transportation facilities had to resort to passenger automobiles as a means of transportation, and if the average of 1.48 persons per passenger automobile remained the same, 29 730 additional passenger vehicles would be required. The streets could not possibly accommodate this additional load. Thus, it will be seen that mass transportation is a vital element in the traffic problem of Youngstown, as it is in any large city; and that, in any plan of traffic control and regulation, its requirements must receive due consideration, as must the effect of its operation on the free movement of traffic.

Mr. Reeder has shown the need for a three-fold attack upon the traffic problem involving the use of engineering, enforcement, and education. A balanced traffic improvement program must include all of these methods of approach.

---

[9] "Traffic Planning Report—Youngstown, Ohio," Jensen, Bowen & Farrell, Engrs., 1937–38.

In conclusion, the first consideration that any city should give to its traffic problem is the efficient use of its present facilities. Minor physical improvements often may be made to the methods of control or to the street system, which result in making the present facilities more useful and more efficient. In planning for future facilities, the basic facts concerning traffic movement should be studied carefully and taken into consideration in developing a traffic-planning program. If traffic control and enforcement are to be successful, all users of street space must be made aware of their responsibilities, one to another, and educated to the safe and efficient use of these facilities.

ROBERT A. MITCHELL,[10] ESQ. (by letter).—In any discussion of this paper one must keep in mind the enormous scope of such a subject and realize that it is impossible to cover even the most important problems fully in such a small space. This is understandable when one realizes that entire books have been written on the subject.

Considering the limitations, Mr. Reeder has presented a sufficiently clear picture so that those who peruse it can obtain an adequate idea of some metropolitan traffic problems, their bearing on social and economic life, and how such conditions may be alleviated. On the other hand, the writer questions the accuracy of certain statements; for instance (see "Helping Traffic Through Danger Spots"), Mr. Reeder infers there is a widespread belief that a city street is "a continuous scene of human and mechanical disaster." On the contrary, the safety problem is so difficult to correct because very few people have seen, or been involved in, a traffic accident, and thus do not take sufficient interest in the subject. It is also unfortunate that more factual data and examples were not used to substantiate certain assertions, because civil engineers have analytical minds and are impressed by facts and figures.

Under the heading "Helping Traffic Through Danger Spots" the author presents, admirably, the advantages of careful engineering planning in making streets safer by designing, locating, and operating traffic signals, signs, and markings so as to take the "guess-work" out of driving. A person could probably learn to run a locomotive as easily as he could a motor vehicle, but no one would think of letting him run that locomotive even a mile along the track unless he knew all the rules of the road and had carefully planned signals to guide him.

The importance that Mr. Reeder attaches to accident records as basic functional data for correcting "bad spots" cannot be stressed too greatly. However, some who have had practical experience in handling traffic problems in a large city find that there are many "mix-ups" that must be solved by past experience and personal judgment. These are mostly problems of congestion and delay rather than those of hazard.

Careful engineering planning also plays an important part in decreasing delays which, Mr. Reeder states (see "Synopsis"), defeat, in part, the purpose of street traffic. From a practical standpoint, citizens seem just as much interested in having traffic officials "clean up" points of serious congestion as accident "sore spots." The author's discussion of by-passing through traffic, parking, and loading and unloading conditions yields an insight into some of the factors causing congestion and indicates practical methods of correcting the situation; but, there are other phases worthy of consideration.

---

[10] Traffic Engr., Dept. of Public Safety, Div. of Traffic Eng., Philadelphia, Pa.

A well-designed traffic signal system, for instance, accelerates traffic, reduces delays, and eliminates congestion, in addition to simplifying the traffic movement, and reducing accidents. When Broad Street in Philadelphia, Pa., was controlled by police at each intersection, the usual sight was a solid mass of vehicles for ten or fifteen continuous blocks—a condition breeding congestion and accidents. Under a proper signal system, over-all speed was increased, the volume of traffic increased, and accidents decreased. Vehicles now travel in small successive groups, often called "waves" or "platoons." In addition, the timing can be altered each day so as to favor the heavy inbound traffic in the morning and the peak outbound traffic in the afternoon. On one of the other down-town streets, the traction company's daily records show that the delay time of their trolley cars has been reduced 18% by the operation of a progressive signal system.

A little white or yellow paint applied in the right places can also help in reducing delays. Unless three lanes of traffic are definitely marked off on each half of Broad Street, motorists will only drive in two lanes, thus reducing the capacity one-third. There are also many examples of increasing the capacity of intersections to handle traffic by the installation of proper laning. Sometimes certain types of cement, rubber, or metal markers are used instead of paint.

Congestion on streets carrying a large volume of traffic can often be alleviated by creating one-way streets or establishing other convenient adjacent routes. Two parallel and adjacent streets in Philadelphia, both with 44-ft cartways, were two-way for many years and carried considerable arterial traffic. In spite of some public criticism, these streets were made one-way in opposite directions and to-day (1939) each of them is carrying about 80% more traffic with less congestion and delay. Traffic on another important artery was relieved by smooth-paving an adjacent granite block street with asphalt, and building, at small cost, a few connecting streets.

Safety zones at street-car stops allow motorists to move by the trolley while it is stopped for passengers; channelization islands at certain intersections reduce conflicts and speed up traffic movement; at highly congested points where land values are not too high, traffic circles and grade separators are sometimes used to improve conditions and there are several examples of parkways and elevated highways in New York, N. Y., Chicago, Ill., Newark, N. J., Philadelphia, and other cities, where millions of dollars have been spent to relieve traffic congestion.

Mr. Reeder made no truer statement than that: "The pedestrian problem is one of increasing seriousness" (see "Protecting the Person on Foot"). While the number of car occupants killed in traffic accidents in large cities has been steadily decreasing, the proportion of pedestrian fatalities has increased until to-day (1939) such deaths represent approximately 75% of the total. In the space allotted, the author has covered the subject admirably well particularly the need for selective education.

Paper after paper has been written on the value of adequate street lighting in improving metropolitan traffic problems. Fact after fact has been presented by experts to show the proportionate seriousness of night accidents over day accidents and to prove that the improvement of illumination in certain cities and on certain highways greatly reduced night accidents. Nevertheless, most public officials are doing almost nothing to improve street lighting in metropolitan areas and the writer does not believe they will until money becomes more plentiful, and there is a strong public demand.

Mr. Reeder "puts his finger" on what is probably the greatest difficulty facing public officials in their attempt to correct traffic problems in the business districts of municipalities; that is, "One of the fallacies that must be exposed and overcome is the feeling that is often held by merchants and business people that traffic density is a good sign of business prosperity" (see "Reducing Traffic Concentration"). Counts made in one large city in 1938 show that on the average, a street car carries 30 people, a bus 15, and a private car less than 2 into the central business district; and yet, merchants continually bring pressure to bear on the law-making body to defeat regulations designed to make it easier for mass transportation riders to reach the shopping district.

Motor vehicles of to-day are smooth running machines which move along the road at reasonably high speeds without any apparent effort. This has made speed control a real problem since most motorists fail to realize how fast they are traveling. Mr. Reeder has explained, adequately, some of the methods for coping with the situation, such as speed zoning and signal systems; but neither of the solutions will be effective unless, as he says, they are reasonable, adequately "sold" to the public, and based on engineering investigation. One of the main reasons that speed zoning has not been effective is that unreasonable speeds were established and then the motorists were given to understand they could travel about 10 miles faster before they would be arrested. During the last year of the 40-mile speed limit in Pennsylvania, state authorities even published the fact that motorists would not be apprehended unless they drove faster than 50 miles per hr. In another case, police officials informed the writer that they never apprehended a driver unless he drove faster than 30 miles an hr through a speed zone posted for speeds not greater than 20 miles per hr. How can one expect motorists to obey regulations that the officials themselves do not believe proper? Establish a reasonable speed, enforce it to the letter, and then motorists will respect it, and other laws. Most of the credit for Pennsylvania's reduction of traffic fatalities in 1938 is given to the absolute enforcement of the speed limit of 50 miles per hr adopted in the latter part of 1937.

Herein, the writer has introduced data to show the importance of mass transportation carriers, which substantiate Mr. Reeder's assertions as to "the street space used per person carried" (see "Mass Transportation") by various types of vehicles. With the increased use of private vehicles, the problem of mass transportation is increasing, both financially and from a standpoint of congestion. There has been considerable controversy as to whether or not buses will supplant street cars entirely because they are more mobile and seem to interfere less with the general traffic movement. One thing is certain: Quick pick-up, more speed, and faster stopping ability must be the qualifications of modern transportation vehicles.

Although Mr. Reeder hasn't covered all the problems faced by municipal traffic authorities, the toughest of which is "public relations," he has given enough information to impress the reader with the immensity of the traffic problem and to show that it will not be solved by trial-and-error methods but by adequate traffic planning based on engineering principles.

Cleveland B. Coe,[11] Assoc. M. Am. Soc. C. E. (by letter).—The point most forcibly "brought home" by this paper is that traffic control is now a specialized branch of engineering, calling for the usual engineering procedure of assembling all available facts, analyzing them, and creating a rational design according to tested rules. The rules will continue to be more or less empirical, as the human element plays a greater part than in the design of structures. Efforts in the past to force traffic, both wheeled and foot, into certain channels have failed to a greater or less degree, and the solution lies in the education of the individual, on the one hand, and in making traffic rules and channels easy and natural to follow, on the other.

It required centuries to educate the public to the employment of engineers in structural design; and in the fields of highway location and construction, and land surveying, as well as others, the process of education is still going on, with results showing in proportion to the density of population of any section of the country. It is a clear function of technical societies to educate the public, as no individual can do so. Neither can headquarters of a national group reach the civic consciousness of the voters of the many cities, with the possible exception of a few of the larger ones, where in all probability experts are already in charge of the problem, driven thereto by the exceeding seriousness of the situation.

This is a matter for local sections and local engineering clubs. Each one should have a committee working through local publicity channels, with subject matter furnished by their own investigations and by central headquarters. They should not confuse their objective with an attempted solution of local traffic problems, but should educate the local authorities to the point of employing a traffic engineer, first laying the groundwork by educating the voting public and the press to approval of this course.

The importance of this groundwork cannot be over-estimated. Time and again in all fields, notably in City Management, the employment of experts has been tried and abandoned for just such lack of support, the voters objecting most strenuously to bringing in an outside expert, no matter whether one was available in the community or not. It is just such lack of understanding and intolerance of the democratic process that has caused most engineers to be exceedingly ineffective politicians.

An interesting fact revealed by the data in the paper is the apparent numerical relation between licensed drivers and pedestrian fatalities. The decrease in fatal accidents in 1938 is encouraging. It may be attributed to the widespread campaign of education. No doubt part of it is due to the education of the younger generation in the proper handling of a high-powered dangerous weapon and their general knowledge, when on foot, of the limitations in driver judgment and mechanical equipment. Many writers have commented on the psychological change that occurs in an otherwise courteous and well-behaved individual when he or she slides under the wheel of an automobile, and it is to be hoped that the coming generation will be so gradually accustomed, from childhood, to the control of so much power that no sudden change of habit will occur when the legal driving age is reached.

---

[11] Associate Highway Engr., TVA, Chattanooga, Tenn.

Education of the public as to the by-passing of through traffic and limiting storage of cars on pavement provided primarily for moving traffic is a more difficult problem and one requiring much time to effect. Cities in the more densely populated Eastern States have apparently learned their lesson through bitter experience, and highways are now being routed around centers of population. Cities in the Southern States are still in the stage where the merchants complain loudly against any proposal to take through tourist traffic off of Main Street. This attitude seems to be not so uncompromising of late, but it is still thought necessary by many that parking be unrestricted in front of their doors. Facts on parking are comparatively easy to ascertain, and only facts will convince the merchant that little or no trade comes to his store from a car occupying valuable space in the street.

It should be noted by those who argue that expensive pavement is laid for moving traffic and not for storage that, regardless of restrictions, the public will "pull over" to the curb and stop, if only to discharge a passenger, and that only one or two, doing this in a block, occupy a lane against moving traffic almost as effectively as a line of parked cars. Since this lane is not available anyway, its use should be divided among the drivers as far as practicable and this means limited parking. The use of parking meters to assist the regulating officers is still on trial, some cities and merchants approving them after trial and others having discontinued their use. Here again personal bias and prejudice play a part far too great, whereas the facts could, and should be obtained by an engineer and a report rendered which should quash, effectually, all opinions based on preconceived notions, always excepting those held by people who cannot be reached by fact and reason. All of this emphasizes the importance of employing a trained engineer who cannot only gather the facts but can analyze them and present a summary and conclusions in a form that any citizen can understand.

EARL J. REEDER,[12] M. Am. Soc. C. E. (by letter).—The discussions by Messrs. Herrold, Buckley, Mickle, Mitchell, and Coe amplified the original paper in a very effective manner. Although little difference of opinion has been expressed, some questions have been raised which will be treated herein.

Mr. Herrold is quite right in his statement that "the accident-prone driver presents a problem with which the careful driver cannot cope." There can be little doubt that the person who, through improper driving habits or unwillingness to conform with the requirements of traffic safety, becomes repeatedly involved in accidents is a menace to others who want to drive or walk safely. However, accident-proneness, as indicated by the repetition of accidents, does not appear to be a characteristic of a very large percentage of drivers. In fact, T. W. Forbes, of the Bureau for Street Traffic Research at Yale University, states[13] concerning a study of 29 500 drivers from the State of Connecticut for the years 1931–1936 that "We are thus left with the conclusion that not more than 1.3 per cent of the drivers were accident-prone and that only 3.7 per cent of the accidents in the states studied could be attributed to the accident-prone driver."

---

[12] Chf. Traffic Engr., National Safety Council, Inc., Chicago, Ill.

On the other hand, many street locations are definitely accident-prone as indicated by the repetition of accidents of almost the same kind. Analyses of many hundreds of collision diagrams of street intersections, and other problem locations, have shown definite patterns of accident experience at individual locations. In many cases these patterns are not at all similar to the traffic-flow pattern, for they show vehicles from certain directions predominating in the accident experience and those from other directions having little or no part in it. Surely, one cannot conclude that the careless drivers come from only one or two directions and that the drivers approaching from other directions are careful. Rather, the only conclusion that can be drawn in such cases is that there is something unusual and unanticipated about the condition to which the drivers and pedestrians are subjected from certain approaches. Further evidence of this is found in the fact that corrective measures often result in the prevention of these accidents by simplifying the traffic and making it easier to drive or walk safely.

Mr. Mitchell's interpretation of the statement "Contrary to the belief of many, a city street is not a continuous scene of human and mechanical disaster," is somewhat different from what was intended, and some explanation should be made. The purpose was not to convey the impression that a great many people over-estimate the seriousness of the traffic-accident problem. That certainly is not the case. It was intended, rather, to mean that many believe that accidents are rather indiscriminately distributed along the street and are likely to occur almost anywhere. In fact, however, they are concentrated at certain points and along certain sections of streets, whereas other sections are relatively free of accidents.

The difficulty with the belief of many, as the statement was intended to convey, is that it would place the responsibility for accidents too largely upon abnormal or unsocial drivers and pedestrians who are not interested in their own safety. However, the patterns of accidents at individual "high-accident" locations, and the freedom from accidents of long sections of street bearing the same traffic that becomes involved in accidents at other places, show quite conclusively that a substantial part of the responsibility for accidents lies with the conditions peculiar to individual locations.

The very basis of the engineering approach to the solution of traffic problems is the belief that the vast majority of drivers and pedestrians drive or walk safely to the extent that they can foresee and avoid hazards. The function of traffic engineering is to make it easier for drivers and pedestrians to use the streets and highways safely and expeditiously either by eliminating the hazards or by providing warnings, safeguards, and aids for avoiding them where they must remain. The more effectively this function is performed, the easier will be the functions of traffic-safety education and enforcement.

---

[13] *Journal of General Psychology*, April, 1939.

The field of traffic engineering has the very fascinating job of determining and evaluating driver and pedestrian practices as important factors in the design of traffic facilities, control measures, and safeguards. The more quantitative data that are gathered concerning traffic the more obvious it becomes that driver and pedestrian practices, under similar conditions, are approaching similarity. Vehicle speeds along a given section of street will fall into quite definite patterns, the dissenters from which are likely to be relatively few. Nearly all drivers will obey a "stop" sign where the computed "critical speed," as determined by view obstructions and other conditions, is very low. However, where the critical speed is relatively high, a much smaller percentage will obey because the others resent restrictions which are obviously unnecessary. These and other facts which traffic engineers observe enable this branch of the profession to design measures for the prevention of accidents and congestion and to obtain anticipated results.

Another important function of the traffic engineer is to make the results of his efforts to reduce accidents or congestion on existing streets or highways serve as the basis for foreseeing and preventing similar conditions in the design and construction of new ones. It is the assembly of that body of information concerning the value of different remedies for different problems and the conditions which differentiate one problem from another which will give to his proposals for avoiding accidents or congestion in new street or highway plans the prestige which comes from successful experience.

Fortunately, in setting up a new traffic-engineering department in a city, the engineer can start with treatment of the many accident or congestion problems that already confront him and work from them to the treatment of the problems which he foresees in the new streets or highways that are being planned. As time goes on, his job will change somewhat from the treatment of existing problems to the anticipation of those that will develop if the proper measures are not taken in the design and construction of improvements or new streets or highways.

THE YELLOW RIVER PROBLEM

By O. J. Todd,[1] M. Am. Soc. C. E., and S. Eliassen,[2] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. J. W. Beardsley, Elliott J. Dent, Herbert Chatley, H. van der Veen, C. S. Jarvis, E. W. Lane, George Higgins, and O. J. Todd and S. Eliassen.

Synopsis

The river problems of North China, aggravated by serious floods and heavy silt loads, have perplexed the Chinese for more than 4 000 yr. Especially has the Yellow River taxed the ingenuity of their hydraulic engineers, as shown by the numerous changes of course this river has taken across the Great Plain of North China through recorded history, changes that have meant appalling disasters to the population of the plain. What Western engineers have learned in recent years about its many-sided problems is outlined in this paper. Such evidence as is available is offered to indicate that certain phases of the Yellow River problem are much clearer to-day than they were in 1919 when the first attempts were made by Western engineers to probe into the hydraulics of this exceptional river and suggest methods for its control and regulation. Proposals for a general regulation program are also outlined, based on the most recent investigations. These proposals give promise of more adequate flood insurance for the population of the Great Plain than has existed previously. Since 1919, both writers have been connected with organizations, such as the Yellow River Commission, the Chihli or North China River Commission, and the China International Famine Relief Commission, all of which have been concerned with investigations of this river in a modern way. Data presented in this paper have been gathered by these Commissions, or under their direction unless otherwise mentioned.

Introduction

The Yellow River is unique among the larger rivers of the world in that, during freshets, it can carry a silt load that may reach 40% by weight where

---

Note.—Published in December, 1938, *Proceedings*.

it enters the alluvial plain of North China. The effect of this high silt load is to raise the river bed gradually, a phenomenon which can be divided into two distinct actions: (1) That in the upper reaches of the diked course, caused by the silt load itself; and (2) that in its lower reaches, due mainly to a flattening of the slope produced by the extension of the delta into the shallow Gulf of Chihli. The two actions, as far as they affect the rise of the river bed, overlap each other, and there is no distinct border line between them. Changes of the river's course through the delta may have far-reaching influences up stream in some years, much beyond the back-water influence of the tides; but the effect of such delta changes may be completely obliterated a year or two later, by the arrival of highly silt-laden freshets, or by dike breaches. The seaward growth of the delta is thus only partly responsible for the steadily increasing super-elevation of the river's course above the plain.

Locally, the gradual rise of the river bed (which averages about 3 ft per century) can often be as much, or more, in a few years time; but such deposition may again be partly scoured out during following years. This creates an exasperating river-control problem in that the dikes must be raised continually, sometimes as much as 5 ft or 6 ft, over lengths as great as 20 to 30 miles, and it may happen that dike sections recently raised must again be built up after a couple of years due to local deposition. It is an ever-continuing struggle to keep the height of the dikes ahead of the river. Often the river wins, overtops and breaks the dikes and, for a time, wanders unfettered across the densely populated plain causing immense damage and loss of life. Under such circumstances, it is impossible for the vast region on both sides of the Yellow River to develop.

The Yellow River flows on a ridge and is elevated above the plain through which it runs. Once it has broken its dikes, therefore, it will not, as a rule, go back to its low-water channel of its own accord when the flood is over. It remains outside and must be brought back to its course forcibly. This is a classical procedure in China and the person supervising it derives much credit if he is successful. If he fails, this is his misfortune. It may even cost him his life; but no glory accrues to the person who watches the dikes skillfully and keeps them intact. He is merely a "work horse."

That the Chinese have tried various methods of controlling this troublesome river, during the course of time, is evident, and the books and pamphlets dealing with its history and control are myriad; but, unfortunately, they have mostly been written by scholars who knew more about poetry than rivers. It is said of the great Emperor Yü (2200 B.C.) that he solved the problem of getting the river to flow in a bed below the surface of the plain. This skill seems to have died with him, however, and ever since attempts to do so have failed. Since Yü's time discussions regarding control methods have generally fallen into two groups—the diked single-channel method, and a system of multiple channels combined with irrigation and broad flooding when the freshet season is on. In practice, it has usually been a combination of the two methods. During the last ten centuries the single-diked channel method has been adhered to as far as the river has allowed.

The modern conception of channel contraction to induce a more concentrated flow with greater velocities to scour the channel is not new to the Chinese. History tells of much heated discussion among river engineers regarding the good and bad points of a single channel and a system of several channels. In the Ming Dynasty (A.D. 1368–1644), Pan Chi Hsun was the outstanding proponent of the single-channel theory. Already in his time the river was mainly held to a single, diked channel; but he had more advanced ideas and wanted a channel as narrow as possible in order to carry the silt and the floods to sea. His more conservative opponents advocated a wide distance between the dikes for storage of silt and for dissipating the floods. They said:

> "If the dikes are far apart there will be fewer places where we must defend the dikes by costly works and the dangers will be few. If the dikes are too close together the foreshore is easily washed away, the dangerous places will be many and the cost of protecting the dikes will be very great."

This argument holds to-day and has been taken up by Western engineers, as witnessed by the proposals of the late John R. Freeman, Past-President and Hon. M. Am. Soc. C. E.,[3] by German engineers who have later visited the Yellow River, such as Professor L. Franzius, and by the laboratory experiments made in Germany for the Chinese Government in 1932 and 1934, experiments which do not entirely uphold the narrow-dike, distance theory.

One of the real obstacles to progress, of course, lies in the lack of hydraulic knowledge of the river itself. Until a relatively few years ago very little hydraulic data existed. This is now being overcome and gradually "light is being shed" on many of the perplexities that have shrouded the river in mystery and have made it subject to more superstition, perhaps, than that with which rivers in China generally are endowed.

There is probably no river in the world which is of so little use to mankind as the Yellow River considering the populous districts through which it flows. Thus far, people have been only partly successful in protecting themselves from its ravages. Even as a communication artery it is unimportant. The river is an enemy instead of a helpful agent. The task of making it obey the commands of Man is a most fascinating challenge to the Engineering Profession.

SCOPE OF INVESTIGATIONS

Former Studies.—For more than half a century foreign engineers and others of scientific leanings have interested themselves in the problems of the Yellow River. The great breach that occurred in Eastern Honan in 1851 (see Fig. 1), causing this river to leave its southeasterly course to the Yellow Sea, and changing it permanently to a northeasterly direction emptying into the Gulf of Chihli, 400 miles to the north of its old mouth, was of pronounced significance. It was the year 1868, however, before a foreign investigator visited the site and prepared notes for publication telling of the effects of this channel change and discussing the various problems involved.

---

[3] "Flood Problems in China," by the late John R. Freeman, *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1405.

The studies of the break of 1851 and that of 1887 by Ney Elias and, later, by G. J. Morrison (British), Gen. J. H. Wilson (American), Messrs. Shermbeek and Visser (Dutch), and others at various times over a period of 25 yr from 1868 to 1893, need no special remarks. The findings of these engineers and scientists, as well as those of Capt. W. F. Tyler in 1902, have been commented upon by the late Mr. Freeman.[3]

The mapping work made in the upper reaches of the river by European travelers and geologists such as Richthofen, Tafel, and Filchner (Germans), Obrutschew (Russian), D'Ollene (French), and others, are of much geographical importance, being the main sources for defining the western drainage boundaries of the river. The geological findings of Pumpelly, Richthofen, Baily Willis, and lately of the Chinese and foreign geologists of the China Geological Society, are of the greatest value for understanding and furthering the engineering problems of the Yellow River.

Among the engineers of modern times, Mr. Freeman must be cited as the first who has gone into the flood problems of the Yellow River with such zeal and intelligence as to make his paper on "Flood Problems in China"[3] a contribution of outstanding value. He had devoted much time to a careful study of all the more important records extant. In connection with the Grand Canal improvement plans which he came to China to supervise and complete, he had an unusual opportunity to have certain important data gathered, tabulated, and mapped. It may fairly be said, therefore, that the systematic investigation of the flood problem of the Yellow River, in a modern sense, began with Mr. Freeman.

Studies in Recent Years; General Surveys.—Prior to the autumn of 1933 the control of the Yellow River, where it ran through the plain, had been in the hands of the Provincial Governments of Shantung, Chihli (later Hopei), and Honan (see Fig. 1). These Governments had their own survey systems, differing in co-ordinates, scales, and elevation datums. Independent of each other they managed as well as possible, and the political and financial questions to be solved generally outweighed the technical ones. However, one Chinese Government organization in Tientsin (the Chihli River Commission, which was investigating the river problem of the Province of Chihli on account of the silt and flood situation affecting the City of Tientsin and its navigable river, the Hai Ho) took an active interest also in the Yellow River since this river had a direct bearing on the port problem of Tientsin. Centuries ago, the Hai Ho (river) from Tientsin to the sea was the outlet of the Yellow River into the Gulf of Chihli, and it is not unlikely that it again may take this course. The Chihli River Commission, therefore, began its own independent studies in 1919, had its engineers run level lines down to the Yellow River at various points, and established two hydrometric stations on the river, one at Lokou, 150 miles from the sea, and one at Shanchow, in Western Honan, 600 miles from the sea. Although involving the observation of the river only at two places the data collected have been very valuable in that, at least as far as water-level observations are concerned, they have been uninterrupted since 1922 in spite of all civil wars, and they have been continued to date (1938) by the Yellow River Commission, a Chinese National Government organization

which was established in the autumn of 1933. (In all recent studies of the Yellow River the so-called Taku Datum (T.D.), named after the Village of Taku at the mouth of the Hai Ho which passes through Tientsin, has been used as elevation datum. It is a zero reference plane corresponding to the low water of spring tides at the mouth of the Hai Ho. The Grand Canal Improvement Board, in its studies of the Grand Canal and the Yellow River, used the so-called Tsingtao Datum which corresponds approximately to zero elevation of extreme low tides of the ocean at Tsingtao Harbor. The relation between Taku Datum and Tsingtao Datum near Lokou is approximately: Taku Datum minus 5.25 ft equals Tsingtao Datum. Taku Datum is 4.50 ft below mean sea level.)

The hydrometric investigations by the Grand Canal Improvement Board during the spring, summer, and autumn of 1919 covered water level, discharge and silt observations, and studies of scour and refill of the river bed at two sections near the Grand Canal crossing. Furthermore, its engineers surveyed the dike system of the Yellow River between the Peiping-Hankow and Tientsin-Pukow Railways, all being engineering data (including cross-sections) pertinent to the Grand Canal improvement problem.

Yellow River System

systematically collected hydrometric data at a point on the Yellow River 12 miles down stream from Paotou in Suiyuan Province in connection with the Saratsi Irrigation Project. Other irrigation projects constructed between 1930 and 1935, drawing water supply from tributaries of the Yellow River (such as from the King River in the Province of Shensi and the Fen River in the Province of Shansi), naturally necessitated the study of these rivers and the knowledge thus gained contributed to the general understanding of the Yellow River problem.

A more ambitious program of investigations has been conducted by the Yellow River Commission since October, 1933. This Commission has conducted hydrometric studies at fifteen stations along the main river and at sixteen stations along the more important tributaries. These stations are shown in Fig. 1. In addition to the hydrometric work a detailed topographic and hydrographic survey has been made of the entire course of the Yellow River through the plain, including the sea coast outside the delta. This survey, mapped to a scale of 1 : 10 000, with contour intervals of 1.64 ft (0.5 m), covers the area between the dikes and approximately a 5-mile strip outside. The total area surveyed is about 9 500 sq miles. It has been linked to the topographic survey of the former Chihli River Commission, later the

Hua Pei River Commission. This was easy to do because the survey of the Yellow River Commission has been patterned closely after that of the Chihli River Commission.

In addition to the more precise mapping work in the plain reconnaissance, surveys have been conducted along the upper reaches of the river from Lanchow in Kansu down stream to Hochu in Northern Shansi, a distance of more than 1 000 miles.

Hydraulic Laboratory Experiments.—In order to reach some conclusions regarding the much-discussed question of increased erosive force of the river if the distance between the dikes were decreased, the Chinese Government had certain hydraulic laboratory experiments conducted in Germany in 1932 and 1934. The first set of experiments in 1932 were made with the channel straight and the dikes set back so that the width ratio between foreshore : channel : foreshore was approximately 3 : 2 : 3; whereas for the "narrow-dike-distance" experiments, the dikes were set close to the edges of the channel. In the experiments of 1934 the channel was made moderately winding. In one of the experiments the dikes were made straight and were located so that they nearly touched the outer concaves of the winding channel, and in the second experiment they followed the winding channel closely. In the first of the two winding-channel experiments, low, straight "wing-dikes" had been built out from the main dike, and followed one bank along the tangents which connected the channel bends, in order to guide the flow as much as possible along the curved channel, thus preventing it from flowing across the foreshores except at high stages. The idea was to concentrate most of the flow along the curved channel, with relatively sluggish flow over the foreshores, so that deposits would tend to form there, whereas the channel would be scoured.

Although no very decisive conclusions could be drawn from the experiments the results gave some startling indications. With the dikes set far apart a somewhat better scour was produced in the channel (with a considerable amount of silt deposition on the foreshores) than when the dikes were close to the channel edges. In the experiments with curved channels the wing-dikes seemed to have had the desired effect of silting the foreshores without raising the bed of the channel; in fact, a slight bed scour was discernible. Noticeable silting of the channel occurred, however, in the experiments with the dikes following the edges of the channel closely. It should be remarked that the kind and quantity of silt used, the length of the flood and low-water season, and the intensity and duration of the flood flow, were assumed quantities and bore little relation to those of the Yellow River. Therefore, the experiments indicate only, in a general way, what the results are likely to be if dikes are built close to, or far from, the banks of a silty river.

When the results became known they had the effect of postponing any moving of the present dikes closer to the banks of the river. A highly silty river does not seem to act quite according to customary hydraulic assumptions or calculations, and in this respect the experiments were illuminating. Since they were made the hydraulics of the Yellow River had become better known, and further laboratory experiments may give more specific results regarding the reaction of the river to contemplated control measures.

Soil Erosion Experiments.—Base surveys have been made of gullies and sloping lands where the erosion is severe, with a view to conducting experiments with soil retention measures, both structural and agricultural, on sloping lands as well as in the gullies. Since the silt is the "stumbling block" to nearly all conservancy measures on the Yellow River, it is evident that, in the future, soil-erosion control will assume greater and greater importance.

FORMER ATTEMPTS TO COPE WITH THE FLOOD PROBLEM

Such records as are trustworthy show that for many generations (at least during the past 1 000 yr) the Chinese have depended chiefly on their dike system as a means of controlling floods on the densely populated Great Plain. Inspection of old banks of former river courses, such as those near Techow in Northern Shantung, where the river ran during the Tenth and Eleventh Centuries A.D., indicates clearly that earth dikes were the principal means of keeping this troublesome stream within bounds. Likewise, was its control within one channel for the 500 yr preceding the break of 1851 effected by a single line of strong dikes. Practically no evidences remain of stone work being used to protect this dike system, of which plain remnants exist below the point of the break 30 miles east of Kaifeng. Records reveal that when dikes did give way in places the breaches were repaired by a prodigious use of kaoliang stalks, hemp rope, willow stakes, bags of clay, etc. This method of closing a breach has gradually been improved and is used with certain modifications to this day.

Ancient history, perhaps mythical, reveals that the great Emperor Yü divided the flow across the plain into nine channels and by this method succeeded, as mentioned in the "Introduction," in getting the bed of the channels to lie below the surface of the plain. There is evidence to support the belief that the serious erosion period which Northwest China now experiences began about the time of the great Yü and, if this is correct, it is most likely that he would not have had the silt masses to contend with which now are such obstacles to an effective control of the Yellow River. Undoubtedly, it was the increasing silt masses which finally destroyed Yü's work. Since then pandemonium has reigned. Many control methods have been tried to prevent the river from raising its bed, but to no avail. In 1073 A.D., during the Sung Dynasty, a proposal was made by an official and scholar, Wang An-Shih, in which he urged that 1 000 iron scarifiers be used to stir up the mud in the river bed at low-water stages so that it might be carried down stream and the channel thus lowered. His idea was not adopted because it was thought to be too costly and not very promising in result; but it is perhaps the first recorded proposal for dredging in the history of the Yellow River. Pan Chi Hsün and his dike contraction idea, which created such a controversy, has already been mentioned in the "Introduction." On a stone tablet which to-day can be seen on top of Yün Lung Shan (outside the City of Hsüchow, at the crossing of the Tientsin-Pukow and the Lunghai Railways, and on the bank of the old Yellow River course previous to 1851) Pan Chi Hsün has left an inscription which bemoans the fact that his ideas were not understood.

By the middle of the Nineteenth Century the bed had become so high that when the breach of 1851 occurred, it was found impossible to close it, especially as the Taiping Rebellion was raging at the time. The breach is known to the Chinese as the Tung Hwa Hsiang Breach. Due to the great difference in elevation between the river bed and the land outside the dikes the flow rushing out through the breach caused a back-cutting toward the up stream which lowered the river bed for a considerable distance. For more than 25 miles up stream from the breach the foreshore lands now (1938) have elevations which are still higher than the highest flood levels since 1851; and from the Peiping-Hankow Railway Bridge to the Shantung border the river is still actively adjusting its grade as a result of this breach which occurred 87 yr ago.

After ten years of indecision the new course toward the northeast was finally accepted as the new permanent channel of the river; but nearly thirty years elapsed before an adequate dike system had been built which could be said to control the river during years of low flood flow; and even to-day there is great difficulty in keeping a medium-sized flood from overtopping or breaking through the dikes in the section between the 1851 break and the Shantung border.

The most notorious breach that has occurred since the Tung Hwa Hsiang catastrophe is perhaps the one in 1887. It occurred more up stream, between Kaifeng and the Peiping-Hankow Railway Bridge, and, as a result, for two years, the river flowed southeastward to the Huai River and the Hungtze Lake before the breach was finally closed during mid-winter when the flow was exceptionally low. Another serious break occurred in 1921 in Eastern Shantung near the coast when the entire flow of the river left the old bed. The successful closure of this breach, by means of a rock-fill dam, was reported in 1933[4] (see Fig. 2).

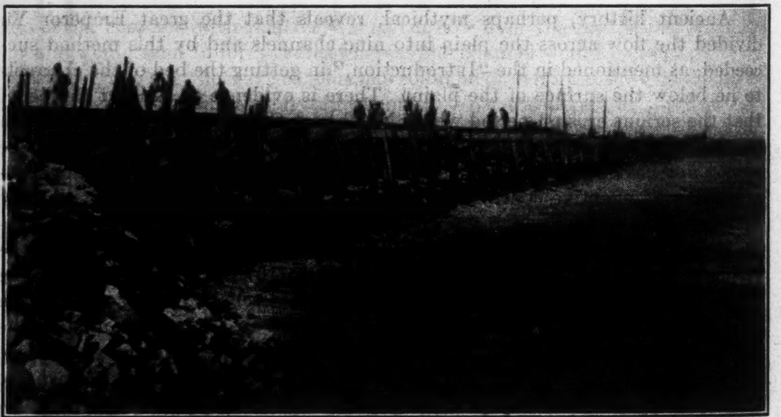

FIG. 2.—COMPLETING ROCK-FILL DAM FROM TRESTLE ACROSS THE YELLOW RIVER TO DIVERT FLOW BACK INTO ITS OLD BED, APRIL, 1923

---

[4] "Wrestling with Some of China's Rivers," by O. J. Todd, *Civil Engineering*, June, 1933, p. 304.

The next major break in the main dikes occurred in August, 1925, in Western Shantung One of the writers made surveys and estimates during the following months and drew up a plan for closure work. The Shantung Provincial River Bureau effected a closure within six months. Fortunately, on this occasion, only one-half the flow of the river had left its bed, running into a low area that emptied into Tungping Lake and from there back to the Yellow River, 75 miles east of the break. It was in this region that the break occurred in 1919 as described by Mr. Freeman.[5]

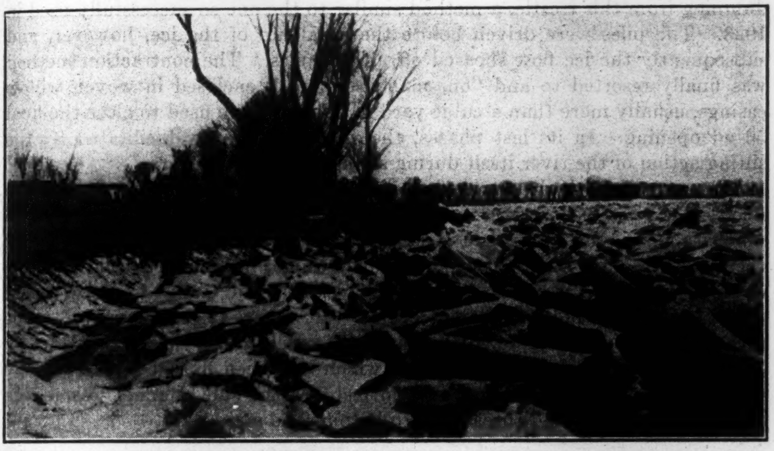

FIG. 3.—ICE JAM IN YELLOW RIVER JUST ABOVE LITSIN, SHANTUNG, FEBRUARY, 1928

In late February, 1928, a heavy ice jam caused ponding and overtopping of the south main dike in two places east of Litsin, Shantung, near the coast (see Fig. 3). This breach was closed within a few months using old Chinese methods; but considerable aid was given by the river itself in that it partly silted up the breach openings. It was in this vicinity, but 10 miles up stream on the same bank, that the dikes failed in August, 1937, during heavy, prolonged summer floods. The region then inundated was estimated at 1 000 sq miles, approximately equal to that of 1928. No attempt has been made to close this breach. The country affected is not densely populated and the land has much alkali. It lies in the lower delta region close to the sea, and sluicing silt on it will convert it into good, arable land, after a few years.

Dike breaks occurred in 1933, 1934, 1935, and 1937. In flood discharge magnitude the year 1933 was the most serious in that the highest flood, perhaps since 1842, then occurred. Between the place of the Tung Hwa Hsiang breach and the Shantung border the dikes were breached in thirty-five places. Several long sections of the north dike were buried in silt so that nothing could be seen except the two lines of trees that grew along the top of the dike. Due to the extremely heavy silt flow of the river the breaches gradually closed themselves except the one farthest down stream on the north bank. This breach, called the Fenglo breach, was closed the following spring by gradually contracting the opening, working from both sides. Originally, it had been planned to build a wooden pile trestle across the opening and close it by stone-dumping from this trestle, a method similar to the one so successfully used in 1923. The piles were driven before the break up of the ice, however, and subsequently the ice flow sheared off all the piles. The contraction method was finally resorted to and "one-man-sized" rock enclosed in woven willow casings, usually more than a cubic yard in volume, were used to close the final 50-yd opening. In its last phases, the work was greatly facilitated by the silting action of the river itself during a small spring freshet.

---

[5] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), Fig. 5, p. 1414.

The 1933 flood had destroyed so much of the dike system that when the flood season arrived in 1934 a 10-mile section of the dike, abutting the northern end of the Tung Hwa Hsiang breach, remained to be rebuilt. Since there was an outer dike (the Golden Dike) which, in case of overflow, would deflect the escaped water back into the river near the Grand Canal crossing, the situation was not considered serious. However, 1934 also proved to be a year of high floods and, in August, a side channel toward the north gradually developed across the former dike line which had been buried in silt; and by the time the flood season was over in October the side channel was taking nearly half the flow and threatened to become the main river.

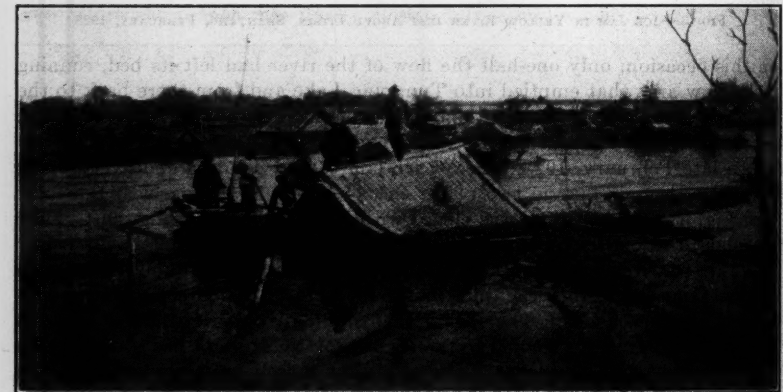

FIG. 4.—A VILLAGE IN SOUTH HOPEI BURIED IN SILT BY A YELLOW RIVER DIKE BREAK, MARCH 1, 1935

The Golden Dike was seriously endangered and if it should break the flow would most likely go to Tientsin. A major closing operation became necessary. An attempt was first made to contract the opening sufficiently by layers of kaoliang stalks and earth so that a plug of the same material could be lowered into the opening. This could not be wider than 80 ft if one were to be sure of success. Unfortunately, the river bed proved to be very sandy to great depths and became deeply scoured when the opening had been contracted to

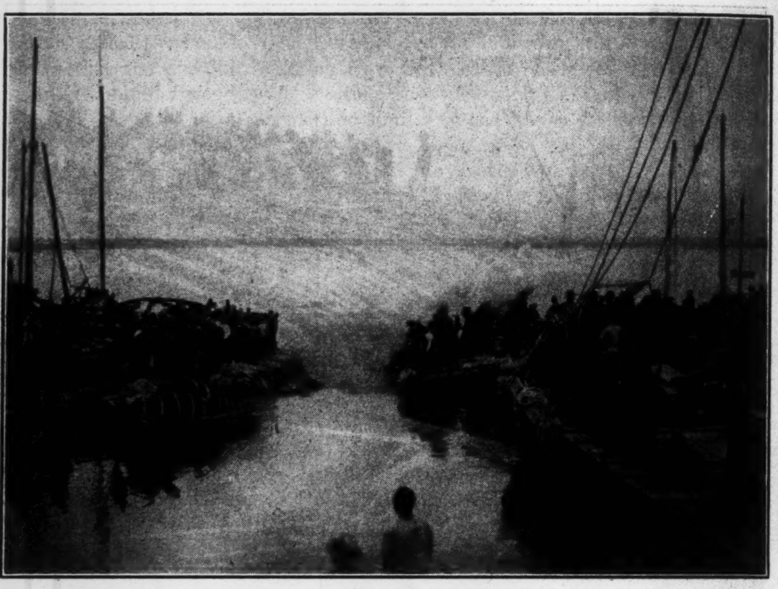

FIG. 7.—PLACING LAST STONE "SAUSAGES" TO CLOSE BREACH OF 1935, AT TUNGCHUANG, SHANTUNG, ALONG SOUTH BANK OF YELLOW RIVER

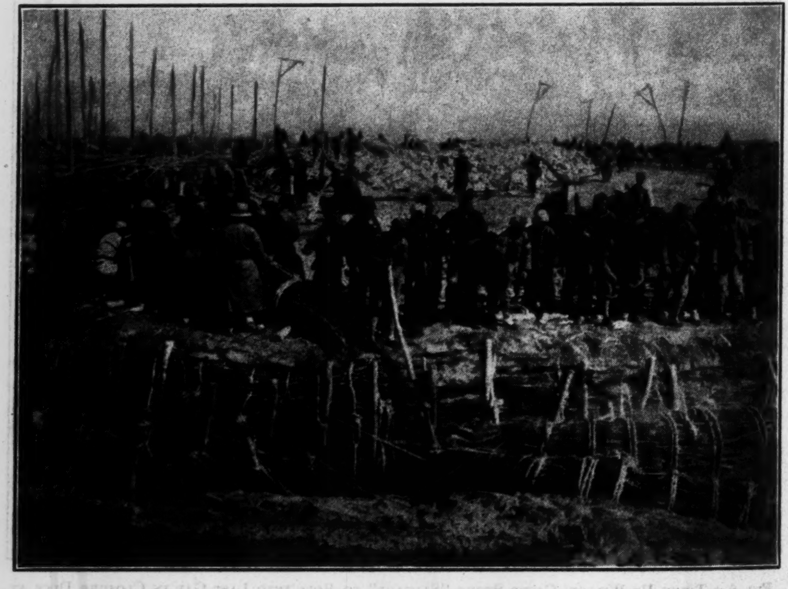

FIG. 8.—WILLOW STONE "SAUSAGES" AT TUNGCHUANG CLOSURE HELD IN POSITION AGAINST HEAD OF 5 FEET OF WATER BY THREE OR FOUR TWISTED WIRE CABLES AFTER HEMP ROPES FAILED

about 120 ft. The ends of the closing work became undermined, broke off, and floated away like great haystacks, and no further progress could be made by this method. Soundings showed depths of nearly 70 ft. Finally, the river bottom was sealed by the use of long fascines made of woven willow matting wrapped around an inner core of rubble and tied together with hemp rope. As in the case of the closure work at the Fenglo breach, the river threw a silt bar in front of the opening during a silty spring freshet and the final closure work could practically be done in quiet water.

The break at Tungchuang, in Western Shantung, the following year (1935) proved by far the most disastrous since the break of 1887, because it inundated approximately 6 000 sq miles of farming country in Western Shantung and Northern Kiangsu, the flow going to sea at a point near the former mouth of the river during the five centuries prior to the change of course in 1851. Fig. 4 is a view, taken March 1, 1935, of a village in South Hopei. Before the end of 1935 the entire flow was pouring to the southeast through the breach. The Shantung Provincial Yellow River Bureau began the work of closure; but after two months of preliminary arrangements the National Government set up an organization that assumed charge of the task, and completed the closure successfully by the end of March, 1936. In connection with this work the writers were engaged as Assistant Chief Engineer and Consultant, respectively. Benefiting by the experience gained during the Fenglo and Kuant'ai breach closure works (the Chinese refer to the 1934 breach or side-channel closure as the Kuant'ai work), stone was used in much larger quantities, and after the breach opening had been contracted to about 130 ft, with a maximum depth of about 40 ft, work was begun immediately to seal the river bed and prevent it from being scoured further (see Figs. 5, 6, 7 and 8). The fascine "sausages" were made about 3 ft in diameter and from 40 to 60 ft long, and they were considerably larger than those used at Kuant'ai. The discharge during the time of closure averaged 30 000 to 35 000 cu ft per sec, but in spite of this rather heavy low-water flow the work proceeded without any serious setback. In the last three days, during the final closure, the river had to be "headed up" more than 6 ft in order to force the flow back into the old channel. This was facilitated by a cut-off channel 3 miles long which short-circuited a 10-mile sharp bend immediately below the breach and acted as a "primer" for accelerating the scour action in the old channel.[6] Fig. 9 shows a stone rip-rap apron with a woven willow cover, tied back by twisted wire ropes to hold small stones in position until silt fills the voids. A kaoliang wall tops the dike with 2 ft of earth cover. Fig. 10 shows a bent protected by a loose brick toe held by wire mesh.

PHYSIOGRAPHY

The Yellow River has its origin in a series of lakes and swamps on a plateau in Eastern Tibet. Before it reaches China proper it has cut its way through the mighty mountain ranges of the Kuenlun in a series of magnificent gorges. Reaching the Province of Kansu it receives its first important tributary, the Tao Ho, from the southeast. Then passing Lanchow, the capital of Kansu,

it cuts through the most easterly spurs of the Nanshan Mountain Range and flows out on the plains of Ninghsia. Here, the course widens and islands and shoals appear everywhere in the channel. Forming the border between Ninghsia and Suiyuan it is again hemmed in by low mountains before emerging on the Suiyuan Plain.

It is typical of all the rivers in North China that they flow through a series of gorges and basins, the slope being flat through the basins and steep through the gorges. The basins are overflow and depositing areas for the loessic silt which the rivers carry in freshets and the gorges are cut through denuded mountain ranges where the rocky surfaces are exposed. The main basins of the Yellow River are in Ninghsia and Suiyuan, and between Lungmen and Tungkuan. However, there are many smaller, intermediate basins, such as at Chungwei, in Kansu. The alluvial plain of North China may be regarded as the last basin. The gorges first extend from the plateau near the source to Kansu, through which Province the river runs in a series of shorter gorges. Where it follows the Ninghsia-Suiyuan border it has a shallow, but remarkably steep, sloping gorge. From the Suiyuan-Shansi border to Lungmen the entire course is gorge like, and, finally, the last gorge extends from Shanchow to where the river enters the alluvial plain of North China. The slope through the gorges is often steeper than 1 : 1 000 with occasional rapids and waterfalls; through the basins (such as the Suiyuan Plain) the slope may be flatter, locally, than 1 : 10 000, but usually it ranges from 1 : 2 500 to 1 : 3 000.

Through Ninghsia and Western Suiyuan, for a distance of more than 400 miles, the river has practically no tributaries. This region is arid, with an average rainfall of scarcely more than 5 in. per yr; but, as it leaves Suiyuan and enters the north-south course between Shansi and Shensi the river receives numerous tributaries from both sides. These carry little flow during the dry season from November to June, but during the rainy season in summer they may be raging silt torrents. Then, at Tungkuan, where the course bends abruptly toward the east, its most important tributary—the Wei Ho—enters. The Wei Ho has many small tributaries draining the lofty Chinling Mountain Range which flanks it closely on the south. From the north, draining the loess plateau, it has only a few, but highly important tributaries. From Tungkuan to where the Yellow River enters the plain the tributaries are also numerous, but, as is the case between Tungkuan and Suiyuan, they carry almost no flow during the dry season whereas in the rainy season they are of much importance. Especially notorious flood carriers are the two streams, the Lo Ho from the south and the Chin Ho from the north, which enter the main river just up stream from the point where the dike system begins.

Besides the Chinling Mountain Range which forms the divide between the Yellow River and the Yangtzekiang drainage areas, the Liu Pan Shan Mountain Range in Southeast Kansu should be mentioned. This range has a north-south direction. It stands directly in the way of easterly rain-bearing winds and thus causes copious, orographic rainfall on the head-waters of the King Ho, the most important tributary to Wei Ho from the north. Table 1 gives the distances and elevations of a number of points along the river, which have been definitely connected by surveys and leveling.

The drainage area of the Yellow River above the Peiping-Hankow Railway Bridge is 294 000 sq miles (756 000 sq km). Some geographers like to include also the tributaries that belonged to it when it had a different course to the sea than it has now, for example, when it was flowing north to Tientsin or south to the Yellow Sea. In such case, its drainage area would be increased about 65%; but at least for the time being one must assume that the river will most likely be kept to its present course for another century. In that case its area can only be regarded as lying up stream from a point where it enters the fully diked course at the Peiping-Hankow Railway Bridge. To this should be added the Shantung area of about 4 500 sq miles. The exact value to be given to the last area is difficult to determine because during floods the flow becomes divided and much of it does not enter the Yellow River, but flows south into the Grand Canal and the West Shantung Lakes.

The chief characteristic of the Yellow River drainage area is its loess and tertiary clay deposits, which are especially extensive in Eastern Kansu, Northern Shensi, and Shansi. They are found in the river valleys, between the mountain ranges, and exist as a continuous plateau extending from Eastern Kansu across Shensi into the Province of Shansi. Frequently, the deposits have depths of more than 300 ft. It should be noted that the aeolian loess (in Chinese, *huang tu*, or "yellow earth") is a relatively recent deposit. Hence, it is generally the top-soil cover. It is underlaid by the similar, but older, tertiary clay, which, as a rule, is of a more reddish color. Over large areas the loess cover has been entirely stripped off and the red tertiary clay is fully exposed (see Figs. 11, 12, and 13). The tertiary clay is a soil of finer texture than the loess and is more resistant to erosion. Therefore, rivers passing mainly through tertiary clay areas, such as the Honan Lo Ho, as a rule, are less silt-laden after heavy rains than those which pass through areas where the loess cover is still deep.

The origin of the loess, or even the tertiary clay, is a much disputed point. The tertiary clay seems to have filled the valleys as a result of the leveling of the mountain areas throughout the Tertiary epoch, and the loess deposited intermittently toward the end of the Tertiary and the beginning of the Quaternary ages, either blown in from the north or due to weathering of all the mountain ranges which traverse the Kansu, Shensi, and Shansi areas. This was a period of very wet, very dry, and windy, climate when erosion by stream flow and soil deposition by wind alternated. Hence, one may often find the strangest mixture of layers of gravel, loess, and tertiary clay in exposed, high, vertical river banks (see Figs. 14 and 15). Most likely, the present is a period of erosion, as witnessed by the heavy silt load which all the North China rivers carry in the rainy season; but the dust storms that occur in the spring are reminders of the earlier dry periods when the loess cover was laid down. Even now, in less than a day's time, a cover of nearly 0.01 in. of dust may settle on floors and tables in a closed room during a heavy dust storm. Two such storms per year would deposit a 20-in. layer in 1 000 yr and in 100 000 yr (which approximate the duration of the geological periods when these dust deposits were formed), the depth of the deposits would be 167 ft (modified by a suitable settlement factor), which is an average depth of the actual deposits on much of the Yellow River water-shed. As these dust storms always occur when there is a north gale, it seems that there is a gradual shifting of the soil toward the south by the wind; and, as all the rivers flow toward the east, there is also a gradual shifting of the soil toward the east by water action.

To-day the terrain in the loess and tertiary clay areas has become most severely cut by erosion. The farmers are fighting a losing battle against this destruction, and every year they see edges of their land worn away, or the top soil stripped off, by the heavy rain storms, which are so frequent during the rainy season. The entire area has been most extensively, but rather carelessly, terraced, to hold the soil in place, often with good result; but frequently, perhaps due to internecine wars, the terraces have been abandoned. For all practical purposes, the entire area may be said to be denuded of forests if there ever have been forests on it. Trees exist around villages and temples and on some of the more favorable mountain slopes facing northeast; but their effect is negligible in preventing the erosion which is now progressing at an alarming speed.

The Yellow River Basin and the surrounding area, especially its western part, are known as a great earthquake region. To the east its alluvial plain has been built up on a sinking geosynclinic trough, and earthquakes at times also shake this plain severely, as in the beginning of August, 1937. It seems reasonable to believe that the earthquakes are caused in part by the constant shifting of earth loads both by the Yellow River and by the wind from the mountain areas in the northwest to the plain in the east and southeast, amounting to an average probably exceeding 2 000 000 000 tons per yr. That isostatic adjustments due to the accumulating effect of the constant transfer of such huge loads must occur from time to time seems quite evident.

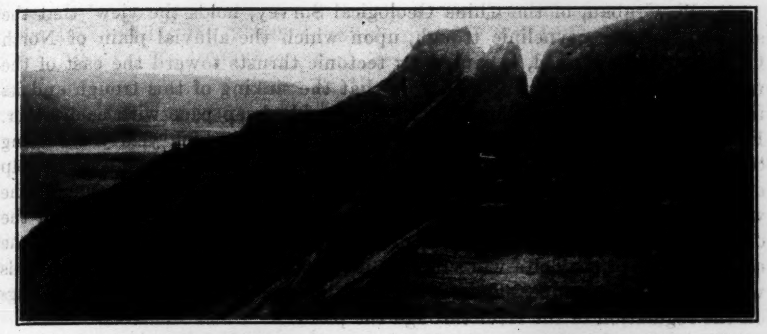

FIG. 14.—A CUT IN LOESS IN WEST SHENSI ALONG MOTOR ROAD FROM SIAN TO LANCHOW, 1932

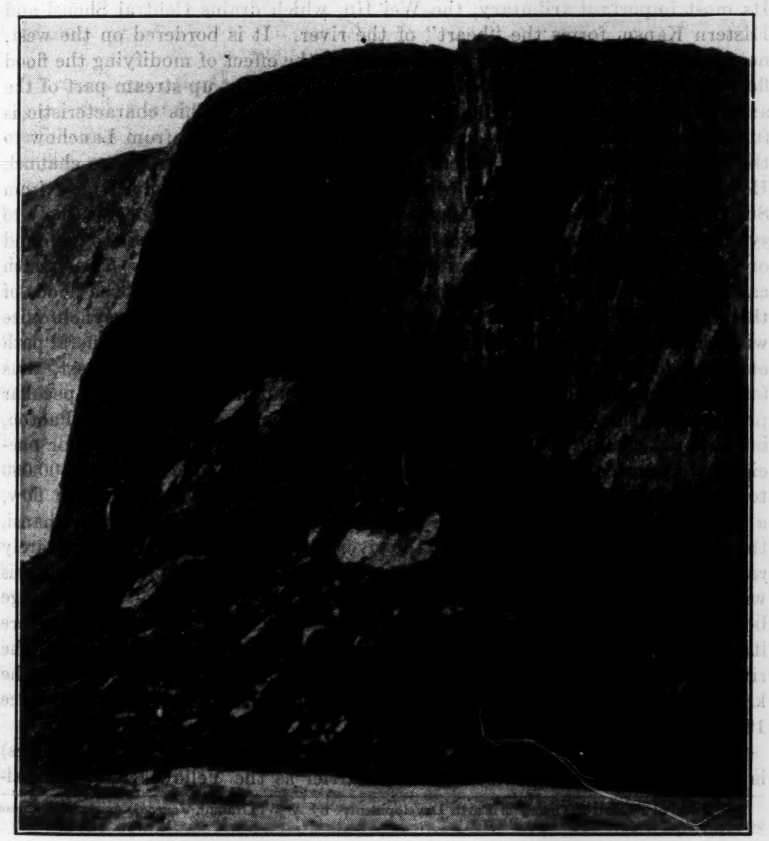

FIG. 15.—A CUT IN LOESS SOIL ALONG NEW MOTOR ROAD FROM SIAN TO LANCHOW, 1932

A. W. Grabau, of the China Geological Survey, holds the view[7] that the sinking of the geosynclinic trough, upon which the alluvial plain of North China has been formed, is caused by tectonic thrusts toward the east of the mountain masses of Central Asia and that the sinking of this trough and its filling, mainly by the Yellow River silt, roughly keep pace with each other. However, it is possible that the enormous silt loads which yearly are being deposited on the North China alluvial plain and its coastal fringe tend to help depress the geosynclinic trough and thus further promote the thrust of the western mountain masses. Furthermore, if the sinking of the plain and the deposition of silt on it keep pace rhythmically, there may be periods when the coastal fringe of the delta will suffer an invasion by the sea, and other periods when it will be built up. These are interesting speculations and have bearings on the regulation of the river through the plain.

The Yellow River is peculiar in the way it encircles a part of its own area. Its most important tributary, the Wei Ho, which drains Central Shensi and Eastern Kansu, forms the "heart" of the river. It is bordered on the west, north, and east by its parent river. This has the effect of modifying the flood flow of the entire Yellow River as floods from the most up-stream part of the area seldom coincide with floods from the Wei Ho. This characteristic is further modified by the flow loss along the 900-mile course from Lanchow to the Suiyuan-Shansi border, where the river is merely a conveyance channel. However, the heavy flood flow which the river can receive on its way from Suiyuan through the 400-mile course down to Tungkuan, at times, is likely to synchronize with the flood flow coming from the Wei Ho. Here is to be found one of the causes for the magnitude of the flood of the Yellow River which can be so destructive in the plain. The other cause is found in the floods of the tributaries—Lo Ho and Chin Ho, in Honan—which also can synchronize with the floods from up stream. This is due to the fact that the general path of many of the flood-producing rainstorms is from west toward east, thus following the flood crest down stream. The result, therefore, is the peculiar phenomenon that one-third of the entire drainage area up stream from Paotou, in Suiyuan, cannot contribute any more than 100 000 cu ft per sec, or one-eighth to one-tenth of the river's estimated maximum flood flow of 800 000 to 1 000 000 cu ft per sec where it enters the plain. As regards the silt flow, a similar situation exists. Where the river leaves Suiyuan and enters Shansi, the maximum silt percentage that the river has been observed to carry rarely reaches 5% by weight; generally, it runs less than 1 per cent. Contrast this with more than 40% at Lungmen, which lies at the lower end of the gorge between Shansi and Shensi, and nearly the same value for the Wei Ho where it enters the Yellow River. These findings regarding the distribution of the river's flood and silt flow are some of the most important contributions to the knowledge of the hydraulics of the Yellow River during the seven years since 1930.

It should be mentioned that the Wei Ho (drainage area, 56 000 sq miles) is almost as important a flood and silt carrier as the Yellow River itself, although it is less important as a low-water feeder. Its most important tributaries are the King Ho (23 000 sq miles), draining mainly East and Northeast Kansu, the Lo Ho (10 000 sq miles), draining North Shensi, and the Hu Lu Ho (5 000 sq miles), draining Southeast Kansu. These three streams all enter the Wei Ho from the north. As the loess and tertiary clay areas lie mostly to the north of the Wei Ho, it follows that the northern tributaries are the silty ones whereas those coming from the Chin Ling Mountain Range to the south may almost be classed as clear rivers, in comparison. The silt coming from the Wei Ho area is, in general, much finer than that coming from the areas in Shansi and Shensi between Hochu and Tungkuan. Partly for this reason freshets from the Wei Ho have a tendency to scour the diked channel of the Yellow River, whereas those from the Hochu-Tungkuan area, containing much coarser silt, tend to raise the river bed. In general, however, freshets from the Wei Ho area have more variation in the intensity of their silt loads than those from the Hochu-Tungkuan area which are always heavily silt-laden.

[7] "The Polar Control Theory of Earth Development," by A. W. Grabau, *Journal*, Assoc. of Chinese and American Engrs., May–June, 1937.

HYDROLOGICAL CONSIDERATIONS

Meteorology.—North China has two distinct yearly climatic seasons—the dry late fall, winter, and spring season with its northerly monsoons caused by the Siberian high-pressure area; and the rainy summer and early fall season with its southerly monsoons caused by the low-pressure area over interior China. In the northern regions of North China the rainy season tends to begin later and end earlier than in the regions closer to Central China. As the course of the Yellow River traverses most of the territory which may be termed North China, its low-water season is shorter and its high-water season longer than the corresponding seasons of the smaller rivers in the north, such as those belonging to the Hai Ho System which converge on Tientsin. The flood season of the Yellow River, therefore, is reckoned from the middle of June to the end of October; but usually it falls between the end of June and the end of September. There is also a brief high-water period in the beginning of April due to release of the ice cover in Suiyuan and North Shansi. From Tungkuan to the sea the ice has already left the river by the end of February, but, where it flows through Suiyuan which lies 5° to 6° farther north, the ice cover does not break up until late March or the beginning of April. At this time ice jams usually form along the flat, sloping course of the river through Suiyuan. These jams may have considerable storage of water behind them. Frequently small freshets from the region above Lanchow occur at the same time. Due to its more southerly location, this section thaws out a little earlier than the river in Suiyuan. Together they form the early April freshets. It should be noted that along the diked part of the river through the alluvial plain a somewhat similar situation exists. The course near the mouth lies near Latitude 38°, whereas the up-stream diked course lies near Latitude 35°; hence, this part thaws out first and causes ice jams in the river near the mouth. These ice jams may be serious enough to break the dikes, as in late February, 1928.

Central China and North China get their rainfall from two systems of cyclonic disturbances, the continental system of low barometric pressure areas which originates in the interior of Asia and which drifts eastward into the Pacific Ocean, and the Pacific Ocean system of depressions or typhoons which generally originates east of the Philippine Islands and which drifts either westward toward South China or curves north and northeastward following the coast of Asia and then back into the Pacific Ocean over the Japanese Islands. These two systems serve to bring into violent contact the dry, cooler air masses of the North Asia Continent and the moist equatorial and South China ocean air masses causing condensation and rainfall. The constant presence of dust in the continental air masses may accentuate the condensation. The south monsoons serve to drive the moist equatorial and Indo-China air masses northward and thus make moisture available for condensation when the depressions arrive on the scene. During the winter the "high" Siberian pressure area, with its strong anti-cyclonic northerly winds, drives moisture southward. This factor, combined with low temperatures, makes the available moisture for condensation and precipitation much less when the depressions arrive from the continent than during the summer, which explains the dry winters and springs although the depressions are numerous enough. Often these depressions merely cause dust storms. When there are no depressions hovering about, there is a gradual tapering off of one air mass into the other. The weather is then generally fine and settled all over China and the typical monsoonal winds blow steadily.

It should be noted that the continental depressions drift against the sources of available moisture in the Pacific Ocean, and, therefore, the rainstorms set up by them are usually short-lived; in the winter and early spring they often cause little or no precipitation. During the summer, however, their drift may be slow, and they may remain stationary for some days causing prolonged, copious rainfall. In order to cause rain on the Yellow River area, the Pacific cyclones must pass close to, or inside, the China coast. Such paths seem possible only during July, August, and early September, and hence typhoons cause flood-producing rain during this period only. The paths of all the depressions are determined by the indistinct contact line of the equatorial—Indo-China and the continental air masses, between which the depressions tend to pass. The primary cause for the rainfall is thus the two opposing air masses; and the secondary cause is the depressions that serve to bring them in contact in such a way that condensation occurs.

To forecast floods in the Yellow River from meteorological observations only seems feasible and may become quite reliable after more study has been made of the various combinations that produce severe rainfall. Considerable study has already been made by the various observatories in China to unravel the rain-storm mysteries; but meteorological stations are lacking in West China and in the regions still more to the west. This has prevented students from forming reliable conclusions as to what climatic combinations will produce the most serious floods in the Yellow River. For the present, flood warnings are sent from "key" hydrometric stations equipped with wireless sending apparatus. This is fairly satisfactory and will generally give 24 to 48 hr advance notice of floods before they arrive at the upper section of the diked course. However, the floods from the Lo Ho and the Chin Ho (which enter the river near the head of the diked channel) constitute a serious difficulty. In July, 1935, the flow at Shanchow was reported telegraphically as 250 000 cu ft per sec, whereas at the hydrometric station just below the Peiping-Hankow Railway Bridge it was measured and reported as 586 000 cu ft per sec. The warnings from the Lo Ho and the Chin Ho came too late and, mainly because the river guards were taken unaware, a destructive breach occurred in Western Shantung. Such flow synchronism, only not so severe, also occurred in the summer of 1937. The flood of July, 1935, was due to a continental depression. A still larger flood of 635 000 cu ft per sec occurred in August, 1935, at Shanchow, traced to typhonic causes. It had increased to only 653 000 cu ft per sec at the head of the diked section.

Little information is available regarding rainfall measurements on the Yellow River drainage area prior to the organization of the Yellow River Commission in 1933. One of the first steps this Commission took was to establish a rainfall-measuring service and, as far as possible, it enlisted the co-operation of the Provincial Governments. Before the flood season of 1934, rainfall was measured at more than 250 stations scattered mostly over the area down stream from Suiyuan, but including the Wei Ho area. Rain-gages, 8 in. in diameter, patterned after the United States Weather Bureau standard, were installed, and it has been possible, from the data collected during 1934 and 1935, to compare rainfall and run-off. The rainfall values have been computed from 1-in. isohyetal maps by the use of planimeters. As the rainfall stations were too few up stream from Paotou in Suiyuan to draw the equal rainfall lines accurately, only the area down stream from this hydrometric station was used and the flow coming from up stream deducted.

The results show a remarkably small run-off percentage. The rainfall from August 1 to 10, 1937, resulting in the high-water period from August 1 to 18, gave a ratio, run-off-to-rainfall, of 13.8 per cent. The rainfall period from August 1 to 10, 1935, as compared with the run-off period from August 1 to 17, had a ratio of 9.2%, and the rainfall period of July 1 to 10, 1935, with a run-off period from July 7 to 13, gave a ratio of 16.1 per cent. The latter storm covered only the Wei Ho area and the Yellow River area down stream from Tungkuan. The flow observed at the Lungmen station and that of the Fen Ho coming from Shansi entering below the Lungmen station were deducted. These data show, conclusively, the effective absorbing power of the loess areas and contrast greatly with similar observations for many of the tributaries to the Hai Ho which drain the more loess-denuded eastern slopes of the Mountain districts immediately west of the plain. Run-off percentages as high as 75% have been observed on these loess areas. Unquestionably, many of the smaller mountain tributaries of the Yellow River can show high run-off rates; but, taken as a whole, the Yellow River has a low run-off rate, which is one of the main reasons why this river, having such a large drainage area, does not yield a higher flood flow than 900 000 cu ft per sec. The Yangtzekiang, up stream from Ichang, with a somewhat similar drainage area, has been observed to have a discharge of nearly 2 500 000 cu ft per sec in a heavy flood.

Frequency and Magnitude of Floods.—Since it is the control of the floods in the plain that is most imperative, one naturally is concerned with the flood flow that enters the diked section of the Yellow River. Hence, the most useful records of flow would be those obtained close to the head of that section. Unfortunately, this flow has been observed only for a few years. The nearest are those for the Shanchow station where practically continuous records are available dating from late 1918. That station is 185 miles up stream from the head of the diked section, and the drainage area down stream is 12 000 sq miles. The latter has several highly important tributaries, such as the Lo Ho (5 000 sq miles) from the south and the Chin Ho (4 000 sq miles) from the north, both of which enter the main river practically where the dikes begin. Unquestionably, the Lo Ho can have flood flows as high as 350 000 cu ft per sec and the diked Chin Ho perhaps as much as 70 000 cu ft per sec. (An automatic control by overflowing the plain before its course has been diked precludes any higher flood-crest flow from entering the Yellow River.) Twice since 1934 the Lo Ho has been observed to have had freshets of 250 000 cu ft per sec—once in 1935 and, again, in 1937. These were exceptionally large floods, however.

It has previously been mentioned that the flow of these two rivers, especially that of the Lo Ho, may synchronize with the flood crest of the main river. Except the flow of these two rivers and other smaller ones belonging to the drainage area between Shanchow and the head of the diked section, however, the Shanchow data record the flow of the entire Yellow River area of 278 000 sq miles up stream from it.

The Lokou records from 1918 to 1937 contain the flow of the river after all losses (such as those from percolation, evaporation, and dike breaches) have occurred. Obviously, they are not very useful for developing a proper flood-magnitude frequency relation. In the past these records have been much referred to as representing the flow of the Yellow River.

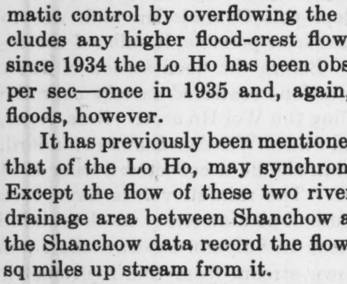

Fig. 16.—Frequency Relation; Yearly Maximum Floods

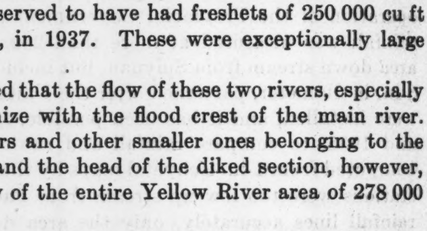

Fig. 17.—Flow Loss Diagram, Yellow River

The duration curves for maximum annual floods have been drawn in Fig. 16, using the 19-yr flow records at Shanchow (1918–1937). It is obvious that, at this point, the Yellow River can have a flood flow exceeding that of 1933, which has been interpolated to have been approximately 812 000 cu ft per sec. Even in 1933 this value could have been exceeded if a closer coincidence had occurred between the freshet of the Wei Ho and the freshet coming from the main river up stream from Tungkuan. The floods are very flashy both from the Wei Ho and from the main river; therefore, a few hours' difference in the arrival of their flood crests at the confluence point at Tungkuan will make a decided difference in the magnitude of the resulting floods passing down the main channel below Tungkuan.

Usually, when the main river has a freshet, there is none, or a very small one, from the Wei Ho—or *vice versa.* As far as has been observed it is the rainfall produced by typhonic causes that tends to bring about simultaneous freshets in both systems. Furthermore, serious floods from typhonic causes are less frequent than those from continental depressions, which generally produce freshets in only one of the systems; but such freshets are again likely to synchronize with the Lo Ho and Chin Ho floods. When floods are produced by typhonic causes, however, the Lo Ho and Chin Ho floods run off first. An extreme flood at Shanchow caused by typhonic influences, therefore, is not likely to be seriously increased by run-off from the area down stream, such as those produced by continental depressions.

As far as can be judged the river is not very likely to have a flow exceeding 900 000 cu ft per sec at the Peiping-Hankow Railway Bridge. To provide for floods greater than this seems economically unsound. This expected maximum flood is about 100% greater than that estimated by earlier investigators. In a long-range forecast of possible maximum floods, perhaps, one should also take into consideration the probability of undertaking drainage-area improvement, such as erosion-control measures. If it proves feasible to reduce erosion to an extent that will decrease the silt content of the river in heavy floods, from 40% to approximately 10%, this alone will reduce a flood of 900 000 cu ft per sec to about 700 000 cu ft per sec by silt removal, not to mention the ameliorating effect which the improvement works themselves may have in retarding the surface run-off and in assisting the soil absorption. Considering the question carefully it seems that 900 000 cu ft per sec is a conservative value to adopt in future design for flood-control measures.

TABLE 2.—MAXIMUM ANNUAL FLOOD DISCHARGES AT SHANCHOW, IN CUBIC FEET PER SECOND

Year (1)	Discharge (2)	Year (1)	Discharge (2)	Year (1)	Discharge (2)	Year (1)	DISCHARGE, AT: Gage (2)	DISCHARGE, AT: Head of diked section (3)

* Dike breach. † Serious dike breach.

The maximum yearly flood discharge of the Yellow River, at Shanchow, for the years 1919 to 1937, inclusive, is shown in Table 2.

Flow Losses.—A matter of much importance for the regulation of the Yellow River is the loss by soil absorption, percolation, and channel storage, along the diked course. These losses are so important that they will figure definitely in the design for the capacity of a regulated channel. The river flows on a ridge with the water level higher, generally, than the plain on both sides; and, the plain itself slopes away from the river toward both sides, which further promotes percolation. Due to the constant dike breaches it is somewhat difficult to reach definite conclusions; but, from the available records some opinion may be formed. Such losses should be observed for various conditions of flow because evidently a high but flashy freshet, lasting scarcely more than 24 hr, is certain to suffer greater losses than another freshet with longer duration. Furthermore, if the river's foreshores are saturated by a recent flood, they will absorb less water than if the foreshores were dry. A silty freshet may or may not have heavier losses than a freshet that is less silt-laden. Heavy rainfall on the wide area between the dikes when a freshet passes down may partly offset losses. These are some of the many factors having a bearing on this question. The loss due to channel storage is a temporary one and its effect is to flatten the flood crest as it proceeds down stream. It is a detention effect only, without loss in volume.

Considering only the diked course from Lokou to Litsin near the mouth, a distance of 110 miles, the average monthly low-water loss in April, May, and June, 1935 (months when the flow was not affected by dike breaches) was 62, 82, and 54 cu ft per sec per mile of river, respectively. As the flow during these months averaged, at Lokou, 39 148, 39 783, and 43 525 cu ft per sec, and, at Litsin, 32 405, 30 886, and 37 736 cu ft per sec, the losses ranged from 13% to 22% of the flow at Lokou, which correspond to average losses in ordinary irrigation channels. Considering the elevated position of the Yellow River with reference to the plain the loss may be regarded as small. Due to complications of dike breaches in the upper course of the diked river and also due to seepage flow from the Shantung Mountains it has not been possible to arrive at any valuable results from that part of the river. The bed is much wider at that part and it is probable that the low-water losses are heavier than for the lower river.

During the flood season it is only to be expected that the flow losses will be relatively greater than during the low-water season. The wide foreshores become inundated and since, as a rule, they slope from the river banks toward the dikes, and usually are well cultivated, this feature will facilitate percolation losses. Much silt is deposited on the foreshores and for every cubic foot of settled silt about 0.7 cu ft of water will be held with the silt. For example, if there is a loss in silt discharge of 10 000 cu ft per sec (dry state) between two points on the diked river it means that, at the same time, 7 000 cu ft per sec of clean water is tied up with the deposited silt. Although small, this loss is a permanent one and may be regarded as part of the percolation losses.

On account of the wide distance between the dikes, the flattening out of flood crests by channel storage is always most marked from near the head of the diked course at the Peiping-Hankow Railway Bridge to the border of Shantung, a distance of 135 miles. As the dike distance narrows it becomes less marked along the next 70 miles to the Grand Canal crossing. (When there are dike breaches up stream, as in 1934, there will be a return flow in the vicinity of the Grand Canal crossing and this obscures the actual amount of loss.) Along the down-stream 185 miles, from the point where the return flow enters to the last hydrometric station at Litsin near the coast, the channel is much narrower and the average distance between the dikes is only slightly more than 1.25 miles against an average width of 4.5 to 5 miles up stream from the Grand Canal crossing. Along this relatively narrow channel, judging by the observed flow data and allowing for observation inaccuracies, the decreases in cresting flow due to channel storage will usually not be great. The lengthening and flattening of the flood crest by up-stream channel storage has already become so marked that any possibility for further modification is practically eliminated. In fact, due to the flattening of the slope, which is quite pronounced up stream from Litsin, there may be a slight increase of the cresting flow at times, due to the overtaking effect. Observations tend to show that this may take place. From these considerations it is evident that the point for determining what the down-stream channel capacity should be under regulated conditions lies somewhere near the Grand Canal crossing because, from this point down stream, there will be a tendency for the flow to remain relatively unaltered. The loss or gain that may occur along the course from the Grand Canal crossing to the sea does not seem to be large enough to warrant any alteration in channel section. The observed losses during flood periods in 1934, 1935, and 1936 have been plotted in Fig. 17.

Assuming that the losses are proportional to channel area some conclusions may be reached as to what the losses will be in a regulated channel of much smaller dimensions than the present unregulated channel. To convey a flow of 900 000 cu ft per sec the average regulated width between the new dike lines will be about 2.5 miles for the upper reaches of the river from the Peiping-Hankow Railway Bridge to the Shantung border and 2 miles from this place to the Grand Canal crossing. The present dike distances for these two stretches are about 6 miles and 4 miles, respectively. The diagram for the upper stretch, using a flood of 900 000 cu ft per sec at the Peiping-Hankow Railway Bridge, gives a flow loss of about 450 000 cu ft per sec and for the second stretch about 200 000 cu ft per sec. The proportional losses for the new channel would then be about 187 000 cu ft per sec and 100 000 cu ft per sec for the two stretches. For rainfall effect it would be conservative to allow only 150 000 and 80 000 cu ft per sec, or a total loss of 230 000 cu ft per sec between the Peiping-Hankow Railway Bridge and the Grand Canal crossing.

It was noted during the flood season of 1937 that prolonged, medium freshets of 300 000 to 350 000 cu ft per sec did not register as large losses as the more flashy freshets. This is to be expected, of course; it has a bearing on the regulated channel capacity for the condition when there are flood-control detention basins in the mountain area west of the plain. The maximum flow that is likely to enter the diked section in this case will probably not exceed 550 000 cu ft per sec, but it may last for more than 24 hr. Under this condition the flow loss between the Peiping-Hankow Railway Bridge and the Grand Canal crossing will probably not be more than 150 000 cu ft per sec and may even be as small as 100 000 cu ft per sec. This will be sufficient control, however, to prevent a flow of more than 450 000 cu ft per sec from passing into the reach below the Grand Canal crossing.

The writers realize that further investigations and study are necessary to solve more conclusively the dependable magnitude of flow losses along the diked channel; but they are of the opinion, nevertheless, that the present observations show that these losses are so consistently present, and so large, that they should be taken into consideration in a control and regulation plan for the diked course. In fact, if they are not taken into account it will result in an over-sized down-stream channel which will be difficult to maintain. Further investigations may show that the values adopted tentatively by the writers are too small.

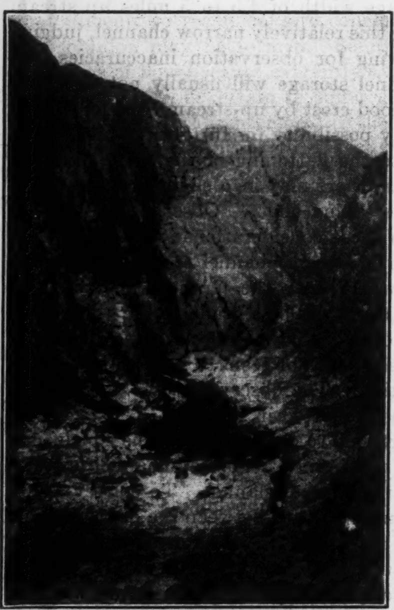

FIG. 18.—GORGE OF THE KING HO, SHENSI, AT INTAKE OF WEI PEI IRRIGATION PROJECT, WHERE MEASUREMENTS OF SAMPLES HAVE SHOWN AS HIGH AS 50% OF SILT BY WEIGHT

Silt Flow.—There is perhaps no important river in the world in which silt is so intimately related to every phase of conservancy work as the Yellow River. Whether it is flood control, irrigation, hydro-electric development, or navigation, the question as to how to overcome the evil effects of the silt overshadows all other technical considerations. This is due to the staggering proportions of the load carried. On other rivers a silt content of 1% or 2% by weight is considered a heavy and obnoxious charge which causes much trouble; but where the Yellow River enters the plain the silt load reaches 40% by weight at times. On several of its tributaries charges as high as 50% by weight have been observed (see Fig. 18). The silt percentage is expressed as: $\frac{\text{Weight of dried silt}}{\text{Weight of water and silt}}$; whereas, the customary method is to express it as: $\frac{\text{Weight of dried silt}}{\text{Weight of filtered water}}$. The first ratio is used in order to avoid such absurd silt percentages as 80%, 90%, or, at times, even 100 per cent.

For computing volumetric silt quantities it has been assumed that the silt density is that of the dried silt ordinarily found on the plain, the weight of which averages 101.5 lb per cu ft (1 600 kg per cu m); that is, its specific gravity is 1.6. Furthermore, from observations based on numerous experimental samples, the average specific gravity of the individual silt grains has been taken as 2.7. Using these values the relation between silt percentages and silt discharges can be developed. Fig. 19, which shows this relation, is used in preference to curves based on experimental data, due to the average condition which the computed curve represents.

Since a knowledge of quantities of silt is more useful than a knowledge of weights, the curve has been made to represent the volume of silt contained in a unit volume of river discharge corresponding to any observed percentage by weight, of silt, in the river discharge, assuming that the silt has been naturally deposited on the plain and has dried. The silt discharge is found by multiplying the number obtained in Fig. 19 by the observed discharge. This curve is very convenient for use when one has to convert silt percentage and discharge into silt discharge a considerable number of times. Most investigators use a conversion factor for computing silt discharge from silt percentages. This may be correct enough for very low silt charges; but, obviously, it gives incorrect results for higher silt percentages since the variation is not a straight-line relation.

Fig. 19 has been based on the assumption that the silt has been allowed to settle, drain, and dry naturally. Therefore, it should not be used for calculations involving silt deposits temporarily settled in flood-control detention basins. Silt settled in water has a volume from 5% to 20% greater than that which the curve gives and a density of 1.8 to 2.1, depending on the character of the silt, time of settling, and depth of the deposits. Loess silt and water become plastic when the percentage by weight reaches 56 to 58. Coarse silt, settled under water, attains a definite volume rather quickly, whereas fine silt continues shrinking for a long period. Hence, each silty stream on which flood detention basin control is contemplated must be especially investigated with regard to its silt-settling action.

In the Yellow River, as well as in other heavily silt-laden rivers of North China, it does not necessarily follow that a maximum flood will have the maximum silt concentration. It may have the maximum silt discharge, however. Several factors determine when the Yellow River will have its maximum silt concentration, some of which are: (*a*) Intensity of rainstorms and area covered by them; (*b*) place where intense rainstorms hit the drainage area; (*c*) dry or wet climatic cycles; (*d*) dilution effect from other parts of drainage area; and (*e*) heavy bed scour during serious freshets.

The most important factor in modifying the silt charge of the river's flow is perhaps the climatic cycle. The silt concentration in the flow has gradually diminished since 1934 and this is unquestionably due to the wetter cycle which began in 1931 and may continue for some years more. It has resulted in a better growth of bushes and grasses over the entire drainage area to such an extent that, during the dry winter and spring, the farmers have not been able to cut the bushes down or to scrape the grass and leaves away completely. This increased vegetation is now holding the soil more securely in place over areas large enough to have a marked influence upon both surface and gully erosion.

The bank erosion along the river channels has probably not been affected; but, in any case, bank erosion is a secondary factor among those which ordinarily contribute to the silt charge as it usually alternates with bank deposition all along the course. On the other hand, channel bed scour may be a very important factor in throwing large masses of bed silt into the stream. For example, in the reach up stream and down stream from Lungmen, in August, 1933, the river bed was deepened an average of more than 15 ft along a stretch estimated at 30 miles. It is unfortunate that no definite record of this extraordinary phenomenon exists other than that obtained from information after the flood. At Lungmen the bed was deepened approximately 30 ft over a width of 3 000 ft, tapering off in depth up stream and down stream. It has been estimated that a silt quantity approximating 7 000 000 000 cu ft was eroded from the river bed along this stretch in a time which cannot have greatly exceeded 12 hr. It demonstrates the capacity of the river to scour in spite of the high silt load it was already carrying. The average discharge during this period seems to have been about 300 000 cu ft per sec. Since this occurrence in 1933 the river bed has again been built up more than 12 ft. A part of this enormous silt quantity was redeposited in the wide river channel up stream from Tungkuan; but, at Tungkuan, and probably down stream toward Shanchow, the bed was again lowered 3 or 4 ft. Similarly, in the plain up stream and down stream from the Peiping-Hankow Railway Bridge, the bed was scoured nearly 6 ft by the same flood that deepened it at Lungmen. At these places the bed remained depressed after the flood, but was partly refilled during the spring of 1935. It seems quite possible that this extra silt load was at least partly responsible for the deposition in the plain which buried the north dike and caused overtopping and numerous dike breaks in August, 1933, below the 1851 break.

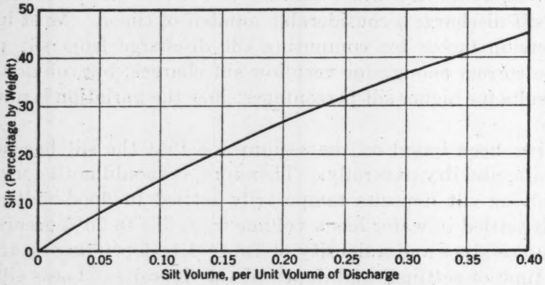

FIG. 19.—CONVERSION OF SILT PERCENTAGES TO SILT VOLUMES IN TERMS OF UNIT VOLUME OF DISCHARGE

However, such occurrences are infrequent. In fact, the inhabitants at Lungmen cannot remember that the river bed has ever been lowered so seriously before. They say: "The river lost its bed"; but old boat fastenings, and iron rings bolted to the rock and uncovered when the bed silt was removed, show that the normal river bed has once been deeper. This points to cycles of silty and less silty periods, which again means dry and wet periods. There is no other stretch along the river where such abnormal action can occur. Regulation of the Yellow River, from the gorge outlet at Lungmen to Tungkuan, with a flood-control detention basin up stream from Lungmen (as is advocated herein under the heading, "Flood Control and Regulation"), will remove, or at least minimize the effect of, such a flood as occurred in August, 1933.

Normally, however, the river receives its silt charge from surface and gully erosion of the loess lands in Kansu, Shensi, and Shansi, and to a lesser extent from Honan. The parts of the drainage area from which the river receives its silt are shown in Table 3.

When comparing the data in Table 3 it is necessary to consider the effect of the dike breach at Kuantai in 1934 and at Tungchuang in 1935. Although the Kuantai breach had no appreciable effect in reducing the silt concentration during the flood season at the stations down stream, it had much effect in reducing them during the low-water season that followed, on account of the clarified outflow from the flooded areas north of the river between the inner and outer dikes in Shantung. The Tungchuang breaches, on the other hand, caused considerable reduction in the silt concentration down stream immediately after the breaches had taken place, due to much deposition between Tungchuang and the Grand Canal crossing and to the clarified flow that re-entered the river at Chiangkow below the Grand Canal crossing.

The daily silt percentages during the freshet season in 1934 and 1935, as they were observed at the hydrometric stations from Shanchow down stream, are listed in Table 4. The sudden increases in silt concentration during freshets, and its gradual diminution and tapering off as the flow passes down stream, is very striking. Table 5 gives interesting silt records gathered in 1934 and 1935 on the Wei Ho.

It has been observed that the river is quite capable of conveying a 12% silt-laden flow of 200 000 cu ft per sec from the Grand Canal crossing to the sea, without any marked deterioration of the channel in that stretch, in spite of the fact that the slope is materially flatter than up stream. It did so during the August, 1934, freshet. The records of this flood are shown in Table 6.

As noted heretofore, the maximum silt concentration does not always occur at the same time as the maximum discharge. Usually, it comes some time after the crest has passed. Quite frequently, however, the maximum silt discharge occurs at the same time as the maximum stream flow. The silt percentages that coincided with the cresting flow are shown as Item No. 3, in Table 6. Actually, the discharge that conveyed the heaviest silt concentration down the diked channel was smaller than the cresting flow. The channel that had been scoured was refilled during the passage of the crest, but not so much as to leave it in any worse condition than during the freshet, except in the reach immediately down stream from the Kuantai breach. It is unfortunate that dike breaks have obscured, somewhat, the happenings along the middle reaches of the diked section. Otherwise, it would have been possible to interpret more accurately the normal action of the river, for instance, with regard to the scour and refill action between the hydrometric stations. All one can conclude for the present is that, at times, it seems deposition can occur in the channel between the hydrometric stations during freshets. Table 4 (*b*) indicates that this perhaps took place between Lokou and Litsin during the August, 1934, freshets, but not to any great extent. The recorded maximum discharge at Litsin at that time is probably too small, and this again would affect the silt discharge. The silt concentration in the flow shows no appreciable change.

The average monthly silt discharges for 1934 and 1935, as they have been computed for all the hydrometric stations along the river below Shanchow, are given in Table 7; the total yearly silt volumes passing the principal hydrometric stations along the Yellow River and the Wei Ho for the same two years, are given in Table 8.

* This station was established in the middle of March, 1935; the March records include only the last half of the month.

The average flow volumes and silt volumes for the periods of the more important freshets occurring in 1934 and 1935 for the three stations Shanchow, Chinchang, and Kaotsun, have been listed in Table 9, in order to give some idea of quantities to be handled in the flood-control detention-basin projects. It will be seen that more than 10% of the flow volume can be silt. The Wei Ho (Huachow Station) measurements in Table 8 do not include the flow of the Pei Lo Ho, which enters the Wei Ho immediately up stream from the confluence

TABLE 6.—REDUCTION IN SILT FLOW, AUGUST, 1934, FLOOD, ALONG THE DIKED CHANNEL

Item No.	Description	Shanchow	Chinchang	Kaotsun	Taochengpu	Lokou	Litsin
1	Maximum stream flow, in cubic feet per second	399 000	494 000	300 000	184 000	191 000	138 000*
	Percentage of Silt:						
2	Maximum value	38.14	18.75	11.42	12.26	10.97	10.92
3	Value of time of maximum discharge	21.00	15.00	6.00	8.50	10.50	10.00
	Maximum Silt Discharge:						
4	In cubic feet per second	60 000	52 000	11 800	10 400	13 400	9 000*
5	Expressed as a percentage of maximum stream flow	15.0	10.5	3.9	5.6	7.0	6.5

* Discharge value is questionable due to poor hydrometric equipment.

* From January to April, inclusive, the flow is estimated.
† Estimated from January to June, inclusive.

point with the Yellow River. Furthermore, the silt flow of the Fen Ho, which enters the Yellow River from the east below Lungmen, is not shown in Table 8. The silt flow of these two rivers will practically account for the rather large discrepancy of 7 500 000 000 cu ft by which the Shanchow Station measurements exceed the sum of those of the Huachow and Lungmen Stations.

Scour and Refill of the Yellow River.—It has been observed that some rivers, flowing in alluvial beds of their own making, tend to scour their beds when the discharge is increasing and again refill them upon a decreasing discharge. In America the Lower Colorado River is an outstanding example of such a self-scouring river. On the other hand, the tendency of the Mississippi River and the Yangtzekiang seems to be to raise their beds when the flow is increasing (at least, at the crossings) and to scour the deposited material when the river is falling. The causes of this difference in behavior are not readily determinable, but the character, quantity, and flow characteristics of the bed material, and of silt in suspension, may be some of the factors.

The Yellow River and most of the other silt-bearing rivers of North China exhibit the same characteristics as the Colorado River, even to a greater extent. In some places the Yellow River has been observed to enlarge its net cross-section, during the freshet season, to more than three times the area it has during the low-water season. However, the question (among many others) arises as to whether this river will stop its scouring, or even begin to deposit its load, when an extremely severe, silty freshet occurs. It is a non-regulated stream without any fixed bed width, being extremely wide and braided in many sections and very narrow in others, and its slope through the diked section varies considerably. It is not easy to predict how it would behave if it were to be regulated and made to flow in a bed of fixed width. The phenomenon of scour and refill, its magnitude, characteristics, dependability under all conditions of silty freshets, and the relation this phenomenon has to the silt transportation, therefore, seem to be of sufficient importance to warrant an investigation as to how far it will influence any regulation plans.

In order to examine the scour and refill action of the river, use has been made of the collected hydrometric data in order to decide whether some conclusions could be drawn. In general, the data gathered to date (1938) show a rapid channel enlargement and deepening upon the rising stage of a freshet and a partial refill immediately after the cresting flow has passed and the flow is receding. After the freshet season has passed there will be a further gradual refill and by the end of the year the bed will have more or less the same elevation position it had before the freshet season began in the middle or end of June or the beginning of July, as the case may be. However, the reach up stream and down stream from the 1851 break is an exception. Here the river bed has been rising definitely during the five years, 1932–1937. In other respects, the scour and refill action is less pronounced in the up-stream reaches than in the down-stream reaches, but local conditions seem to have a considerable bearing on the magnitude of the phenomenon.

When the writers were trying to interpret the data highly dubious cases arose due to lack of cross-section measurements taken just at the time when important changes occurred in the river bed. Due to the long distances between the stations it has been difficult to correlate the happenings at one station with the happenings at the next station; and questions regarding the influence of the character of the bed silt and suspended silt also arose. At times, erosion and refill of the river bed occurred in a manner that could not be explained from the magnitude of the freshets, changes in velocity, the accompanying silt charge, or the rapidity with which the river rose or fell. Furthermore, the condition in the delta seemed to have a strong influence on the elevation of the river bed in the lower reaches. When the delta channel was favorable, the adjacent up-stream channel was deep, and the data tended to show that this increased depth propelled itself up stream by back-cutting until the influence several months later was noted as far up stream as the Grand Canal crossing. This conclusion needs verification by a better correlation of observations, however. The necessary "machinery" for all the investigation work had been set up, but had to be canceled on account of the war.

Some studies have been made of the variation in the effect of silty discharges on scour and refill by plotting silt discharge against total discharge on logarithmic paper for the conditions: (*a*) When the river is scouring its beds; (*b*) when it remains unaltered; and (*c*) when it is silting up. The data, although falling somewhat scattered on the graph, nevertheless show distinct straight line logarithmic relations in all three cases. The lines tend to show that the up-stream reaches of the river at low-water stages are more efficient for conveying silt without channel deterioration than the lower reaches; whereas, for a discharge of more than 90 000 to 100 000 cu ft per sec, the lower reaches become more efficient. These are relatively deep and narrow whereas the upper reaches are shallow, wide, and often much braided.

Variation in slope along the diked course does not seem to have any very decided influence on the capacity of this river to transport its silt or to scour its bed. Perhaps these phenomena may be determined more by the character of the silt (in the bed and in suspension), by the shape of the cross-section, and by the rapidity with which the flood flow increases—that is, by the accelerating force of the flow. Furthermore, the rate of refill seems to depend to a great extent on the rapidity with which the discharge decreases: Rapid decrease means a rapid refill, and *vice versa.* The steady refill back to normal low-water condition in the autumn is probably due to a slow "geschiebe" or bed-load movement when material deposited up stream is gradually moved down stream.

There has not been a chance to observe the scour and refill action during an intense, highly silt-laden freshet; but as far as has been observed a medium-sized freshet, silt-laden to the extent of 18% in the up-stream reaches and 12% in the down-stream reaches, does not seem to have its scouring capacity decreased materially. Higher silt concentrations may show detrimental effects, however.

These are the general conditions. The entire aspect is highly complex, and any silt-transportation and bed-scour formula to cover such multitude of unknowns, does not seem of much practical use. It is realized that more accurate and more specialized data are required to clarify the scour and refill problem. Data should be secured simultaneously at many places along the river with the sole purpose of obtaining the needed information. The river scours and refills so rapidly during freshets that special observation equipment must be organized for such study, including that of rapid silt analysis. Furthermore, the places where the observations are taken should be selected judiciously and should be numerous enough to eliminate possible local effects.

For the time being all that the writers can say with regard to the scour and refill which occur along the diked course of the Yellow River is that such actions do take place at all the five hydrometric stations along this stretch. However, the hydrometric stations have been placed where the river is relatively narrow and stable; no data have been obtained from places where the river is wide and braided, or at typical "cross-overs" between bends. It is possible that at such places there is little or no scour. There may even be a slight fill during the rising stages of a freshet. The possibility of such happenings should not be ignored in the design for a regulated channel. The writers, therefore, advocate cautiousness when it comes to deciding upon widths of a regulated channel for the diked course of the Yellow River.

The laboratory experiments in Germany (reported herein under the heading, "Scope of Investigations: Studies in Recent Years"), although illuminating, are not sufficiently conclusive to warrant any other description than "further experiments."

The gradual refill, especially in the lower reaches, which has been observed to take place in the autumn after the freshet season and which causes the river bed to be brought back to where it was before the beginning of the freshet season, may or may not occur if the channel were to be regulated. The bed-load may then be moved along the bottom more evenly through the diked channel and not, as at present, in fitful stages, first by deposition in the wide up-stream bed and then in another stage down stream. In the reaches up stream and down stream from the 1851 break the river is still adjusting its bed and this also obscures what the actual action would be in the lower reaches if the entire river profile were based on the delta at the sea as the main depositing area for the river through the plain.

FLOOD CONTROL AND REGULATION

Methods of Decreasing Flood Hazards.—As the problem of decreasing flood hazards along the Yellow River through the Great Plain is now analyzed it appears that the remedy should be far more extended than merely to construct greatly strengthened dikes. The remedies that should be considered carefully are the following:

(1) Detention basins west of the Great Plain to arrest temporarily, and to "iron out," the cresting flow of maximum floods;

(2) Spillway flow into basins on both sides of, and near, the river in West Shantung;

(3) A by-pass channel following the general course of the Tu Hai Ho from the Grand Canal crossing to the sea north of the river;

(4) Earth dikes and their protective works;

(5) Channel regulation and fixing a selected course;

(6) Control of soil erosion in Shansi, Shensi, Kansu, and parts of Honan; and,

(7) Control of run-off by increasing the brush and forest cover in Shansi, Shensi, Kansu, and parts of Honan.

Detention Basins West of the Great Plain.—The writers have come to certain tentative conclusions as to the value of detention basins along the main Yellow River above the delta, on several of the feeders from Shensi and Shansi, as well as on the Lo Ho and Chin Ho that enter in Honan at the beginning of the plain. Actual preliminary studies of the gorges below Shanchow were made under the direction of one of the writers in 1935 and 1936. In a paper[8] dealing with flood-control detention basins for the Yellow River, it is suggested that basins in comparatively narrow, steep reaches of the main river are more likely to be successful than any that may be created on the tributaries, due to a more sustained flow in the main river to wash out silt accumulation immediately after the passage of a flood. The aforementioned tributaries, however, have sufficiently sustained flows after flood periods to cause rapid silt removal from the basins behind the dams. Such basins will function both to smooth the flood crests (which are so extreme that they endanger the diked channel through the plain) and to detain a part of the extreme flood silt load, distributing it over a long period.

Beginning 8 miles down stream from Shanchow at the Sanmen Rapids and continuing down stream for 75 miles, the river runs through a series of gorges mainly in limestone formations. Either at Sanmen, or at other points in the gorge (such as at Palihutung), dam sites can be found that would be suitable for use in establishing flood and silt-detention control works. Above the Sanmen Rapids, 200 miles by river, are the Hu-kou Falls where another suitable site for a detention-dam reservoir has been found. This region was inspected by one of the writers and surveyed under his direction in connection with hydro-electric power investigations in 1934. The preliminary studies made of the Yellow River at this point and also those made of the Fen Ho in Shansi, 85 miles north of Taiyuanfu, at Hsiachingyiu,[9] as well as those made by the writers on the Chin Ho, in Shansi, and the King Ho and the Wei Ho, in Shensi, indicate that reasonably satisfactory sites are to be had for an extensive system of detention basins to retard flood discharge. Topographical maps indicate that equally good reservoir and dam sites are to be found in the upper waters of the Lo Ho, in Honan Province; but, thus far, no reliable reports have been made which would definitely show their worth for this purpose of river regulation. The general field has been investigated sufficiently, however, to encourage the writers to believe that the detention-basin feature of flood control of the Yellow River is feasible. Nevertheless, the silt difficulties are fully appreciated.

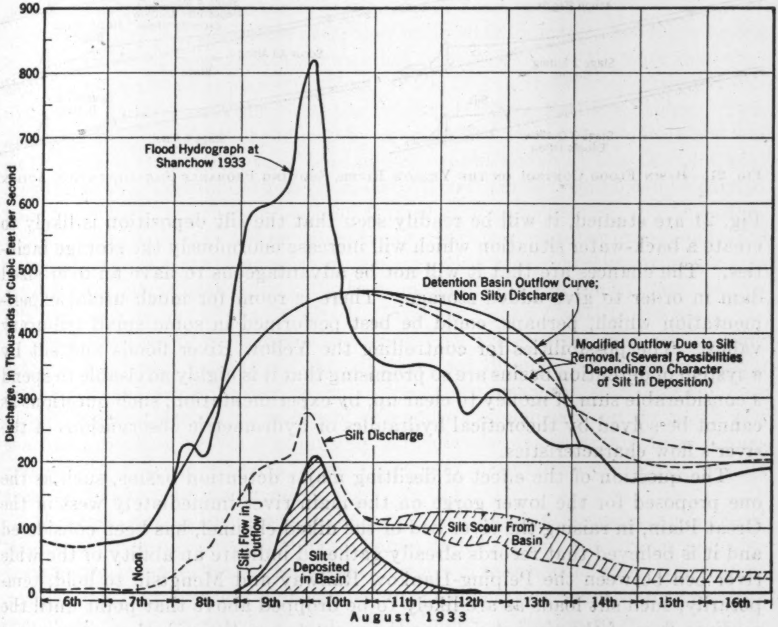

FIG. 20.—SILT DEPOSITION AND OUTFLOW FROM A DETENTION BASIN

Students of this problem generally assume that the openings in dams and canyon walls used for flow control must be ample so that the deposition of silt will not be too heavy in the reservoirs and that the deposits will be removed by scour. This limits the degree of control possible. Due to the complicated nature of the detention action, when there is much silt in the flow, it is not possible to compute, accurately, the data for establishing an outflow curve after the maximum stage has been reached in a basin. That the variations in the outflow and silt-clearing action may be many, can be seen from the diagrammatic sketches, Figs. 20 and 21.

If the basins are selected in relatively narrow valleys, with a slope steeper than 1 : 2 000, so that the normal velocity always will be a scouring one, there need be no apprehension that the basins will not clean themselves; nor is it possible that the large outflow openings may become choked. The important questions are the time element involved in the silt clearing and the height of dam necessary. The time question has a bearing on the possibility of a second large flood following closely on the heels of the first; and the dam question is both one of general security and of economics. If the diagrammatic sketches in Fig. 21 are studied, it will be readily seen that the silt deposition is likely to create a back-water situation which will increase enormously the storage facilities. The chances are that it will not be advantageous to have an over-sized dam in order to give added storage. There is room for much useful experimentation which, perhaps, could be best performed in some small tributary valley. The possibilities for controlling the Yellow River floods and silt by a system of detention basins are so promising that it is highly advisable to spend a considerable sum of money to clear up, by experimentation, such questions as cannot be solved by theoretical hydraulics or hydrometric observations of the river's flow characteristics.

Fig. 21.—Basin Flood Control on the Yellow River, Showing Probable Silt-Detention Action

The question of the effect of desilting major detention basins, such as the one proposed for the lower gorge on the main river immediately west of the Great Plain, in raising the river bed of the diked channel, has been considered and it is believed that records already gathered indicate an ability of the wide river bed between the Peiping-Hankow Railway and Mengtsin to hold, temporarily, such silt loads as are likely to be dropped above that point until the medium flow of the river can carry them out to sea through the autumn and winter months. This section of the river is nearly 75 miles long, is bounded on the south by high loess hills, and only for the last 8 to 10 miles on the north bank are there dikes, which may be raised when necessary. These can easily be protected against any temporary tendency to overtopping due to rapid bed-fill.

The ability of the Yellow River to pick up additional load and degrade its bed even in low and medium stages has been noted when certain local fills, as long as 50 miles, have existed due to new depositions that interfered with the flow unduly. The rapid cutting out and carrying to the sea of the silt filling the channel below the 1935 breach at Tungchuang, Shantung, was observed in late March and early April, 1936, as the closure of the breaches was completed and the river's flow of 30 000 to 35 000 cu ft per sec was forced through the old channel which had been choked with silt left there in the latter part of 1935. As it came into the plain in April (nearly 2% of silt by weight), the spring freshet was not so heavily charged as to prevent its picking up, in the course of a week, the greater part of the fill in this section of the river channel. Furthermore, in the autumn of 1937, a sustained, medium-high flow of 150 000 to 200 000 cu ft per sec, silt-laden to 3% or 4% by weight, had a most potent influence in clearing out bed deposits that had been accumulating for one or two years in long stretches of the river below the Peiping-Hankow Railway. The main river channel is now as free from silt in its upper diked reaches as it was immediately after the series of high-water flows in 1933.

An examination of feasible detention-basin sites indicates that these basins could be relied upon to reduce a maximum crest flow by a little more than one-third (that is, detain a maximum flood of 900 000 cu ft per sec) so that it will not exceed 550 000 cu ft per sec at the Peiping-Hankow Railway Bridge. This discharge would be further reduced by channel losses to approximately 500 000 cu ft per sec at the Shantung border, and would arrive at the Grand Canal crossing with a flow of not more than 450 000 cu ft per sec, which can be carried by the down-stream channel without further control measures. By the adoption of this plan, it may not be necessary to resort to such other expediencies for flow reduction as are suggested in the following text, namely, overflow and desilting basins on both sides of the river in Shantung, and the by-pass channel following the course of the Tu Hai Ho from the Grand Canal to the sea.

Spillway Basins in Western Shantung.—In the control plan for guiding safely a maximum flood of 900 000 cu ft per sec through the regulated, diked section, it has been proposed, as one of the safety measures, to relieve the flow of 100 000 cu ft per sec by means of two spillways, one each on the north and south inner dikes in West Shantung immediately down stream from Tungchuang. If detention basins in the up-stream mountain areas prove feasible these spillways may not be necessary.

However, due to the fact that the river's section near Tungchuang is one of the most dangerous along the diked course under present conditions, and also because one must reçkon with the fact that it will take considerable time before a large-scale improvement plan can be put into operation, since so many points remain to be investigated, it would seem highly advisable to construct such spillways at an early date in order to give added insurance against flood disasters during the period of preparation for the greater flood-control program.

The overflow from the spillways would pass into the areas between the inner and outer dikes, where it would be detained briefly and partly desilted, and then allowed to re-enter the main river just up stream from the Grand Canal crossing after the flood crest has passed the outflow points. Control works to regulate both the inflow and outflow would be necessary. As protection against the attacks of a prolonged flood, it may also be found advisable to have a set of escape sluices in the outer south dike just up stream of the outflow point in order to pass some of the flow into Tungping Lake from which it again would return to the main river at Chiangkou. Additional diking to limit the Tungping Lake area would be necessary. Likewise, there must be a strengthening of the south outer dike. The north outer dike (or the Golden Dike) has already been strengthened in view of the frequent dike breaks that have occurred on the north bank in late years, such as those at Fenglo and Kuantai.

The regions to be used for this purpose are low lying, are amply large, and lend themselves well to a part control of an excessive flow. The only obstacle is the number of villages involved. However, with an improved inner dike system it is not likely that these overflow basins would be used more than once in a decade; nor would the volume of flow into them be very large. The danger of their becoming rapidly filled with silt, therefore, would not be great. Each flooding would be during the summer only and the farmers would thus always be assured of a good spring crop. Often the flooding would not be severe enough to injure the summer kaoliang crop, except in the immediate vicinity of the spillways.

The villages within the basins would either have to be removed or raised. Such raised villages are very common in areas in the North China plain which are subject to frequent flooding and could be promoted with State support. The opposition to be overcome, however, will remain a very difficult part of this control measure. The farmers will submit themselves patiently to frequent chance disasters, but do not wish to listen to any controlled flooding although this may occur less frequently and with less destruction to themselves.

By-Pass Channel from Grand Canal to the Sea.—The Yellow River has no such natural by-pass channel as the Mississippi possesses in the Atchafalaya River. The nearest to it is a small stream called the Tu Hai Ho beginning near the Grand Canal north of the Yellow River and flowing to the sea to the northeast in a course nearly parallel to the main river. It has been suggested that this small stream may be excavated so that it can handle a flow of 120 000 cu ft per sec in times of high flood. Surveys of this project have been made by the Yellow River Commission and advance cost estimates have been developed. The writers have studied the data and feel that the cost of the proposed excavations is somewhat excessive compared to the benefits gained. However, two lines of substantial dikes may be built so that this stream-bed may be used as an overflow channel with a maximum width of about one mile. A suitable modern gate structure would be required near the Grand Canal crossing of the Yellow River to pass flood water from the main river into this new channel. To permit it to function properly it may even be necessary to put a regulator across the main river in order to throw the clearer low-water flow into the by-pass channel when necessary to scour away these silt deposits left during floods.

In case further studies tend to discourage the construction of large detention basins in the mountain districts west of the plain so that floods, after being reduced by channel storage and seepage losses, cannot be held to a maximum of less than 450 000 cu ft per sec at the Grand Canal crossing, it may be found advisable that this by-pass channel should be provided to take a flow of as much as 120 000 cu ft per sec. If it is assumed that a maximum flood will be nearly 900 000 cu ft per sec as it enters the diked section of the river without any modification by detention basins above that point, it may be estimated that not more than 150 000 cu ft per sec will be "ironed out" and lost by channel storage and seepage in the 135-mile stretch to the Shantung border. From a crest flow at that point of 750 000 cu ft per sec, approximately 100 000 cu ft per sec may be diverted to the two adjoining overflow basins in Western Shantung, and a further 80 000 cu ft per sec lost by channel storage and seepage in the next

70 miles. This means that a flow not exceeding 570 000 cu ft per sec will reach the Grand Canal crossing. Here, the proposed by-pass channel will start functioning in the case of an extreme flow. Such a by-pass channel will help in distributing the silt deposits at the coast over a wider area and thus retard the rapid delta building at the mouth of the river.

However, if detention basins in the main river near Shanchow, above Yumenkou, or at Hu-kou, and on some of the larger feeders in Honan, Shansi, or Shensi, prove feasible as aids in reducing crest flows, this by-pass may not be necessary. Assuming that detention basins plus flow losses reduce a maximum flood to 450 000 cu ft per sec by the time it reaches the Grand Canal, the present channel of the main river below that point can accommodate that quantity without any great improvement to that part of the system as it is.

Earth Dikes and Their Protection.—Although dike building has been practiced by the Chinese for more than 1 000 yr, they are to-day behind Western countries in construction methods and safety requirements. On the Yellow River the present earth dikes are not of uniform quality, slope, or width over the 430 miles that they extend from the beginning of the delta plain in Honan west of the Peiping-Hankow Railway to the tidal flats 20 miles east of Litsin; nor are they as scrupulously maintained as they should be, considering the highly important function they perform. Formidable dikes exist for the entire stretch along the north bank; but along the south bank from the Grand Canal crossing to the Tientsin-Pukow Railway, a distance of 90 miles, and from the Peiping-Hankow Railway westward, hills take the place of dikes. On the north bank the dike extends west from the Peiping-Hankow Railway for a distance of about 15 miles.

These dikes are made of loess soil, selected (if the supervision is good) from non-sandy areas and hammered down while wet in 1-ft layers by the use of a 90-lb stone, thrown 8 ft into the air by ropes managed by eight men, the flat surface of such stone being approximately 1 sq ft. By this means the dike is made reasonably tight, and voids that would permit serious leaks are generally prevented. Often the workmen are not carefully supervised, the layers become as thick as 2 ft, and the tamping is indifferently done. Furthermore, sandy soil may often be used with a thin surface layer of clay both for water-proofing and against wind erosion. Leaks through such dikes are difficult to stop and the result is often disastrous. When dikes are reconstructed in winter after dike breaks, frozen chunks appear which cannot be properly pulverized by the light tamping methods, and breaks have occurred from this cause. For these reasons the supervision should be made far stricter than it is at present. No dike construction should be allowed during freezing weather, and such construction can easily be avoided by a better use of the time when the freezing weather has passed. As long as the present light tamping methods are used for compacting the fills, the layers should never be more than 9 in. thick. It would add greatly to the efficiency of the dikes, however, if mechanical compacting devices, such as the American sheep-foot roller, were introduced. When the time comes for regulating the diked channel, the fill must be compacted mechanically or strict rules for construction methods must be enforced if disasters are to be avoided. The new dikes will have to withstand water pressures and swift currents fully as severe as those to which the present dikes are subjected.

As a rule, the main dikes of the Yellow River are 25 to 30 ft wide on top, although some stretches built during the two decades (1918–1938) are as wide as 50 ft. Such excessive widths are partly due to poor, sandy soil, and partly to the fact that in times of high water it may be necessary to utilize the earth from the back of the dikes for making quick repairs. At such times the land outside the dikes is often flooded, due either to rainfall or to seepage, and it is costly to get earth from any other place than the dike itself. Spoil-banks of earth are also frequently placed on top of the dikes for such emergency conditions. These piles of earth which the Chinese call *tu niu* ("earth oxen") are familiar sights to travelers along the dikes. In all new dike work it would be well to follow this practice since, in the flood season, the elevation of the channel above the plain tends to create a swampy or flooded condition along the foot of the dike on the land side.

The present dike slopes are usually from 1 on 2.5 to 1 on 3.5, no uniform rule being followed as to which side should be the flatter. Generally, the dike slopes are covered with an indifferent growth of grass which seldom develops a first-class sod because, during the winter, the farmers rake the surface to gather the wilted grass for fuel and permit their sheep to graze on the dike slopes. Old regulations forbidding such practices are no longer enforced. During times of dike breaches people from the flooded areas crowd on top of the dikes where they build temporary shelters. After the breaches have been closed it is frequently impossible to persuade all of them to leave. Even when the dikes are raised these huts remain, gradually becoming caves in the back slopes with the roofs in some cases even lower than the top of the dike. The desire to live on the dike exemplifies the insecurity of the region along the river.

In recent years an effort has been made to plant willows on the foreshores close to the dikes. This should be encouraged as much as possible because such trees protect the dikes both from wave action and from the high-water currents. Five or more staggered rows of willows with the inner row 20 ft from the foot of the dikes and successive rows 10 to 15 ft apart afford an excellent protection. In the past, trees have been planted on the dikes and this practice still continues. As the dikes frequently have to be raised the trees become a nuisance and have to be removed. The roots remain in the body of the dike and are thus a source of leaks. However, the silty water tends to seal the finer interstices and generally tightens the dikes in the course of time so that this form of trouble is not so serious as it would be if the water were clear. Nevertheless, the potentialities for leaks are there and trees on dikes should not be encouraged.

Slipping of dikes due to excessive saturation is seldom experienced along this river although it does occur on the Yangtzekiang dikes where the clay content is often large and the difference between high and low water is as much as 50 ft at times; on the Lower Yellow River this difference seldom exceeds 15 ft. Dike failure may sometimes be caused by burrowing animals; but less apprehension need be felt for this possibility on the Yellow River than on the Han River near the Yangtze, for instance, where badger-like animals dig holes a foot or more in diameter. Great care should be exercised in watching for these holes.

As the main dike system is frequently a mile or more from the low-water channel the foreshores are inhabited and cultivated, and the farmers living there have gradually thrown up small dikes along the edges of the channel to protect their villages and growing crops against flooding from medium high waters. In times of greater floods these dikes are overtopped and breached, and, as the main dikes are not protected, except where the current constantly impinges on them, the sudden onrush of water has been known, as at Tungchuang in 1935, to set up highly eroding eddy currents which destroy the main dikes. Unauthorized dike work inside the main diking system may thus result in appalling disasters, and, therefore, in future regulation plans, human habitation must be prohibited inside the main diking system and any cultivation strictly supervised. With no villages on the foreshore lands, every one will be interested in keeping the main diking system intact, whereas, at present, there is a considerable number of people who often hope that the main diking system may be breached. The population living on the foreshore lands constitutes one of the difficulties in maintaining the river in its diked course.

Dike Protection.—Since the river channel is not stabilized it meanders at will over the wide strip of land between the dikes. Where the swift eroding currents impinge on the earth dikes it is necessary to protect them. This phase of maintenance work often becomes costly due to the long haul of stone. Stone quarries are few and far between in the Great Plain of North China.

Until a few decades ago when foreign steel became available for rapid quarrying, the Chinese used very little stone for dike protection works. The kaoliang stalk was the chief material used before that time and the kaoliang groin and "fish scale" pack work of the same material, so well described by Mr. Freeman,[3] are still used to a certain extent for dike protection in regions between the Shantung border and the Grand Canal crossing, and also on the lower river near Litsin; but in other regions they are being replaced rapidly by stonework, although for dike-break closure and in emergency cases the kaoliang stalk (Fig. 5) is still extensively used everywhere. Huge stacks of it may be seen to-day piled up near all the maintenance offices, which are spaced at intervals of about 20 miles along the river. Due to the great quantities required kaoliang is not a cheap material to use, and it needs constant maintenance because it rots out in two or three years. New work is then placed on top of the old, forcing the decayed mass into the mud below water where it is readily scoured into by the current. Often it happens that the entire construction is undermined and torn out. As an emergency material kaoliang has its decided place in maintaining the dikes intact, but not for permanent protection. Stone has now become the logical material for this purpose and will probably always remain so since sand cannot be found within reasonable distances for concrete revetment construction on a large scale.

Everywhere along the river, groin construction as defense work against swift currents is preferred to the continuous revetment method practiced on the Mississippi River. Many types of groins are used (see Figs. 19 to 27). One may see the triangular, pointed groin, the narrow, down-stream-pointing groin, and groins rounded in form. They consist of barricades of earth paved with stone and are exactly long enough to keep the current off the dike. In Shantung

they are mostly of the narrow type, the paved sides being almost vertical. A liberal depth of loosely thrown rip-rap covering of one-man-sized stone, protects the groin from under-water attack by the current. All groins are built to be above high-water level. Often an attempt is made to guide the current away from the dike by using one long groin; but this usually has resulted in causing added sinuosity of the river channel with more protection required for the opposite dike which becomes attacked. The "cure-all" effect of the single long groin is firmly defended by the old school of Chinese river engineers which discusses confidently what the river's action will be if a long groin were to be built in order to control a difficult reach. The reason for this optimism is probably due to the fact that the "trick" sometimes has worked without undue harm to down-stream parts. A decentralized control and lack of funds other than for immediate, pressing protection have prevented them from attacking, systematically, reach after reach and thus gradually subduing the river.

Tree retards as an emergency protection (see Fig. 28) are not greatly used along the Yellow River, although one of the writers experimented with this type of bank protection in Shantung in 1922. Trees were used by the Chinese in 1925 at Linpuchi in an attempt to save an earth dike from further destruction. On the Yungting Ho, near Peiping, their use is much more common and has there proved valuable in emergencies. This remedy might be applied more commonly than it has been along the Yellow River.

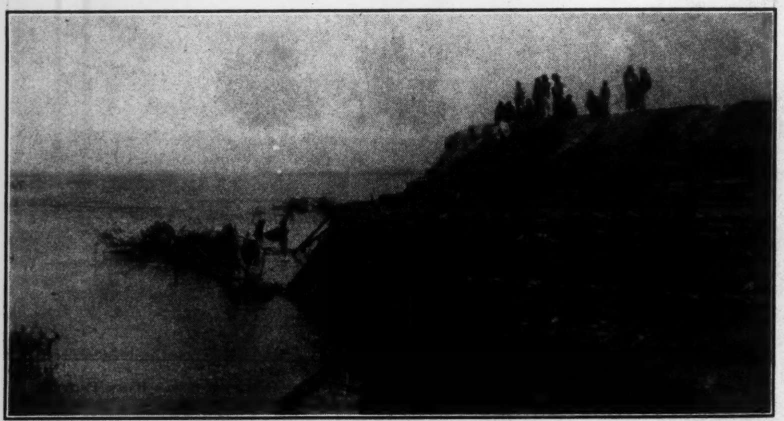

FIG. 28.—USING TREE RETARDS DURING THE 1925 FLOOD IN WESTERN SHANTUNG TO SAVE ERODING BANKS AND DIKES ALONG THE YELLOW RIVER

Regulation of Diked Channel Through the Plain.—Closely related to the problem of maintaining dikes is that of regulating the course of the Yellow River through its diked section. In 1922, Mr. Freeman[3] proposed that there should be a straighter, narrower, and better protected course between two main dike lines than had existed theretofore. His plan was to have two dikes not more than one-half mile apart and protected by regularly spaced groins. It was also his intention to have an inner channel, 1 800 ft wide, regulated and held in a fixed course so that it would be self-scouring and would readily carry all flood flows. Professor Franzius, of Hanover, Germany, using the data collected by Mr. Freeman, formulated an alternative plan in 1931, and recommended a slightly wider central channel, having inner unprotected dikes built along a theoretical mean-water channel expecting to retain the flow long enough in such a course as to make it scour its channel deeper. Each year these dikes would be repaired, but would not be protected in any way. This was a device to obtain a deep, narrow channel at low cost along which permanent dikes with suitable protection might eventually be built, thus stabilizing the channel. These eminent engineers both believed that a narrow channel with dikes built closely along the banks would make the river perform the work of maintaining a deep channel and that it would also scour sufficiently to accommodate the floods.

The hydraulic data that have been collected along the Yellow River since these two engineers discussed its channel regulation have thrown a much better light on the perplexities and difficulties which are inherent in the problem of making a stable, diked channel through the plain. In discussing this regulation problem, two alternative plans present themselves: (1) When the diked channel is to convey the modified, detained outflow from a system of flood-control detention basins within the mountain area to the west of the plain; and (2) when no detention-basin system is feasible and the diked channel must accommodate the full flood flow of the river.

The diked course is not without importance from the viewpoint of navigation and this should be given a certain weight in fixing the dimensions of the regulated channel. Let it be stated at once, however, that protection against flood disasters outweighs so greatly all other considerations that the question of navigation improvement must be considered after the flood-control measures have been fully met.

Under the heading, "Hydrological Considerations: Frequency and Magnitude of Floods," it has been stated herein that the writers consider a flood of 900 000 cu ft per sec to be the probable maximum discharge that the Yellow River can have at the head of its diked course. With a flood-control detention basin system west of the plain it may not be possible, due to the silt load, to reduce this discharge to less than 550 000 cu ft per sec where it enters the diked river. Allowing for channel storage and percolation, and other losses, this flow will most likely not exceed 450 000 cu ft per sec at the Grand Canal crossing, assuming the channel to be regulated. Below this point the present channel, with a moderate degree of improvement, should have sufficient capacity to convey this flow. For a prolonged period during the summer of 1937 it did convey almost this quantity, but finally breached the south dike near the coast due to insufficient bank protection.

Without a detention-basin system, however, the full flow of 900 000 cu ft per sec would have to be accommodated. This flow, it is estimated, would be reduced to 810 000 cu ft per sec at the 1851 break, to 750 000 cu ft per sec at the Shantung border, to 650 000 cu ft per sec by spillways into the proposed overflow basins between the inner and outer dikes on both sides of the river between the Shantung border and the Grand Canal crossing, and, finally, by channel losses to 570 000 cu ft per sec at the Grand Canal crossing. At the latter station the Tu Hai Ho by-pass channel would take away a further flow of 120 000 cu ft per sec, allowing a flow of 450 000 cu ft per sec to pass down the present main channel of the river to the sea. Fig. 29 shows this arrangement. Even if the channel has been narrowed by regulation, these losses do not seem excessive to apply but sufficient foreshore widths must be left to permit them to take place. Even if experience should prove that the final regulated channel does not give such great losses there still remains the expedient of installing light-capacity flood spillways at a few points, such as at the 1851 break, where the old channel still exists, and also below Tungchuang, where the proposed spillway over-flow basins would function for a long period before they became filled with silt.

Fig. 29.—Flow Losses During the Passage of a Maximum Flood Under the Regulated Condition

As regards the distance between the dikes and the width and shape of the actual channel itself conveying the full flow of 900 000 cu ft per sec, there is room for much theoretical discussion. From the considerations of scour and refill, flow and silt losses, and also from the standpoint of the hydraulic laboratory experiments conducted in Germany, it is not at all certain that a narrow channel with dikes built closely along the banks will be the best type to adopt. The German experiments are especially illuminating; they tend to show, in a qualitative or indicative manner, that a channel with dikes spaced far apart scours a little better and silts up its foreshores somewhat faster than the same channel with dikes built closely along the banks. This seems the logical result to be expected. By the transverse circulation of the flow a part of the silt load is transferred from the channel to the wide foreshores giving the less silty flow a better chance to pick up silt from the bed. If there are no foreshores the river has no other chance to relieve itself of its excess silt than by desilting it in the bed of the channel. However, even having a channel with wide foreshores there is certain to come a time when these have been silted up so much that the silt transfer has been reduced to a point where it no longer can influence the flow in picking up silt from the bed of the river. From this time, both the river bed and the foreshores will rise together. Taking a long view of the situation this is perhaps the condition which favors the slowest rise of the river bed. In selecting the width of the foreshores, therefore, it is of little use to make them wider than that required for a normal deposition width. The cross-sections of the river often show a break in the ground profile indicating the line where the heaviest deposition ends. This varies somewhat along the river, but a careful inspection of maps and cross-sections will point out, in a general way, the line to be followed for the best position of the dikes. At times, bad soil condition will make it impossible to follow this line closely, and the best practical route will have to be followed considering every aspect. Judging from cross-sections the indications are that foreshore widths need not exceed 1.25 miles, and, perferably, should be less than this on account of the cost involved in connecting a channel protective system to the dike lines.

There are also other reasons why excessive widths between dikes should be avoided. An outstanding example of detrimental, excessive width is the section between the 1851 break and the Shantung border. At the 1851 break the channel is more than 12 miles wide, whereas at the Shantung border it has been narrowed to about 5 miles. The consequence has been that the banks along the channel, due to the rapid silt deposition, have become as high as the top of the far-away dikes, as indicated by cross-section lines, and differences of more than 10 ft in elevation between the banks and the foot of the dikes have been noted. Generally, the transverse slope of the deposition is from 1 : 3 000 to 1 : 4 000 and hence the flow during freshets, when the foreshores overflow, runs diagonally across the foreshores cutting numerous channels which unite along the foot of the dikes, thus creating a very dangerous situation. It is almost impossible to stop the flow through these side channels once they have developed, and, in time, the river takes up a new channel along the foot of the dike. This has occurred time and again and when it happens the higher flood levels previously existing along the central channel are transferred to the dikes, and overtopping and breaching inevitably occur; hence, the necessity for both a narrower channel and a fixed channel as a link in the flood-control program. With foreshores not exceeding 6 000 ft in width the difference in elevation between the banks along the central channel and the foot of the dikes will be about 2 ft, which is not too much; but practical considerations may reduce this width to about 4 500 ft. The writers do not consider a width less than this to be advisable in the up-stream stretches of the diked river where most of the losses and silt deposition on the foreshores will occur. It may gradually be reduced to 3 500 ft at the Grand Canal crossing. Below the Grand Canal crossing the dikes are not too far apart. They are even too close together in places. The main considerations here would be the straightening out of the existing dike system so that the entire length of the channel would have a more regular dike distance better co-ordinated to the channel itself in order to create a uniform flood profile with easier run-off conditions.

As regards the width to be given the actual channel, Messrs. Freeman and Franzius proposed 1 800 and 2 400 ft, respectively, as most practicable. However, they did not have available data regarding the actual flood flow or silt content of the river, which have been found to be more than twice the values they proposed to adopt.

When the river has a truly silty spell of 40% by weight as was measured during the flood of August, 1933 (812 000 cu ft per sec), there may be some doubt whether it will scour its bed even if this is regulated. The heavy silting which occurred below the 1851 break should be a warning. When designing the regulated channel width, therefore, no absolute reliance can be placed on a hope that the channel will enlarge itself. It seems better to be conservative and give it a width, at least in the up-stream reaches, which will carry the flow without making allowance for scour. The existing channel in the upper reaches of the diked section has widths varying from less than one mile to nearly two miles. At low water this channel is full of sand-bars with many breaches. As the narrower parts are fairly long, and since they carried the maximum flow in 1933 quite effectively, it would seem that under no circumstances should the regulated channel be wider than the narrowest existing sections. From an inspection of the actual conditions it would seem that it would be about right to give the proposed regulated channel a width not exceeding 4 000 ft in the upper reaches, gradually reducing this width to 3 750 ft at the 1851 break, to 3 500 ft at the Shantung border, and to 3 000 ft at the Grand Canal crossing. After the reduction of flow through the Tu Hai Ho by-pass channel a width of 2 000 to 2 200 ft may be sufficient along the entire distance to the sea. This is about the average width of the present channel. It is quite true that the width now at many sections is much narrower than this (as, for example, along the 3-mile stretch at Chiho Hsien, 15 miles up stream from Lokou, where there is scarcely more than 1 500 ft between the protected dikes); but this stretch is too narrow and should be widened. The observed water levels indicate that this section causes a considerable heading up during heavy floods such as occurred in 1937.

When it comes to dike distance width and channel width for the case in which a detention basin system has been built up stream, quite different considerations must be met. In this case the outflow from the detention basin at its maximum, for one or two days, will have a relatively light silt load. As the water level becomes lowered in the basins, the deposited silt begins to be scoured, causing the outflow to be heavily silt-laden. One may be reasonably certain that there will be heavy scour along the regulated channel during the period of less silt-laden outflow, and, therefore, it will be feasible to have a much narrower channel than that required under an assumption of no scour of the channel. A channel width in the up-stream reaches not exceeding 1 800 ft seems amply sufficient; but the same foreshore widths should be kept as in the case of unregulated flood flow. When the silty flow arrives the discharge has already become so low that it will be contained in the channel without flooding the foreshores. Gradually, however, the scoured channel will be refilled and this may again raise the water level and flood the foreshores. Silt will then be transferred to them, and this again will retard further deposition in the channel bed. The swifter velocities in the narrow channel will also help to transport the silt load without undue deposition. Having several detention basins, there will also be silt deposition below each dam as well as along the temporary silt storage area between Mengtsin and the Peiping-Hankow Railway Bridge. This will reduce the possibility of any extremely high silt concentration entering the diked regulated channel as a result of the silt depositions in the basins being scoured out. The rise of the river bed which has been observed in the upper reaches of the diked channel during small, medium silt-laden freshets, is unquestionably due to the present bed, which is far too wide.

The considerations that have been dwelt upon in the foregoing discussion are some of those which unavoidably arise when an investigator attempts to unravel the perplexities encountered in solving the regulation problem of the Yellow River. It will be noted that no attempt has been made to correlate velocities with silt transportation and bed scour. Velocity is only one of the many factors that enter into this problem and cannot be singled out as the safe guiding criterion. Recent studies in mechanics of turbulence seem much more likely to clarify the situation than mere studies of velocities. The writers have tried to use Reynolds numbers to express efficiencies in silt transportation; but the results are meaningless, chiefly on account of the rapidly changing hydraulic radius. For rivers, a different criterion than the Reynolds number must be found to correlate turbulence and its effect on silt transportation and bed scour.

The question of using dredges as an aid in improving the capacity in the river to carry its silt load has been considered. Since the silt which from year to year is left in the channel is small compared with the total silt transportation it may seem worth while to experiment with specially designed, powerful dredges, to see what can be done, before each freshet season, to remove deposits in the channel which would seem to interfere with channel efficiency and hence silt transportation. Dredged cuts, rapidly done, through such deposits may help in their removal by the flood flow when it arrives. Such cuts may be entirely obliterated during the freshet season, but, nevertheless, may have performed their duty in slowing up the rise of the bed. It will be a new departure in the aims of dredging operations and may incidentally assist navigation.

Channel Stabilization Methods.—Until the main dikes have been moved to their designed position in the new regulation plan it will be necessary (since the Yellow River changes its course so rapidly) to construct some cheap, temporary stabilization works to keep the present channel in place until the new dikes have been built and the permanent channel works begun. The actual regulation work should begin near the Grand Canal crossing, each year continuing systematically up stream according to a well-formed plan. Below the Grand Canal crossing the river is in fairly good condition over long stretches, and the main improvements will be to ease a number of sharp bends and bring the dike system to a more uniform width. The existing protection should be utilized to the greatest extent and, as much as possible, be made to fit into the general stabilization plan.

When it comes to stabilizing the much wider channel up stream of the Grand Canal crossing the question naturally arises as to which of the following methods will be adopted: (1) A continuous revetment of the channel banks in the concave sides of the bends and where it is necessary to guide the flow in the cross-overs from one bend to the next; (2) a system of groins; or, (3) a combination of Methods (1) and (2).

Method (3) will probably be the most logical since there naturally will be many places where the banks are fairly stable and will merely require paving and under-water rip-rap for complete stabilization. In such places it will be necessary to construct long groins tied to the dikes. Furthermore, in bends where the flow necessarily comes close to the dike, and where no previous groin work exists, it will be preferable to use the continuous revetment method. Groins in bends create a highly pulsating flow condition during floods and many groins have collapsed from this cause. A certain degree of turbulence is necessary in order to carry the high silt content in suspension, but this should be in moderation. Excessive resistance merely creates higher water stages. The bends themselves unquestionably produce sufficient eddy currents to propel the silt in suspension past the bends and, therefore, a smooth flow around the bends should be sought.

A question of a more difficult nature arises where the channel must be stabilized through reaches where the soil is easily scoured and unstable and the channel far removed from the dikes. Long low groins will be necessary in such cases to protect the foreshore lands and the stabilization works must be tied to the dikes. Several forms of such groins suggest themselves, such as the pile groin, the fascine-stone groin, and the protected earth groin. The first two forms are indispensable where the existing channel must be narrowed, and the earth groin may be used to tie across foreshores, which are dry at medium stages. However, as an earth groin must be above high water to escape destruction, its use will probably be very limited. The guiding principle, in all cases, should be such that silt flow on the foreshore land will be fairly unobstructed in order to give facilities for the channel to scour; but the velocities on the foreshore land must not be so swift that they will tend to scour side channels.

Availability and cost of materials will determine whether the fascine-stone groin should be used to bridge the space between the banks and the dikes, or the pile-hurdle groin. The latter will require a mattress construction along its full length to prevent its being undermined and destroyed. The outer ends of these groins should define the new channel alignment, and should be in the form of stone heads. Since economical considerations make it inadvisable to space these long groins close enough to keep the channel from becoming sinuous, it will be necessary to construct short, intermediate groins to prevent this effect. These intermediate groins may be exactly long enough to be tied to the nearest normal bank or ground, which is above the ordinary summer stages, between freshet periods. As regards the question of spacing the groins, and whether they should be short or long, much depends on the soil conditions. Obviously, a sandy, easily scoured soil requires closer groin spacing than if the soil is of a more erosion-resisting quality.

Experience on the Yellow River indicates that nothing but solid construction work will endure the onslaughts of a flood. Miserable failures have resulted from attempts at constructing light pile groins for flood control. They have been laid flat or rooted up by the silty, swift water, and the great bulk of weed root and kaoliang stalk which the flow carries during freshet periods and which pile on to the works. Anything that remains will be entirely removed by the ice during the late winter. In much exposed places the fascine-stone groins will have the best chances for surviving. They can also be added to readily as the silt accumulates on the foreshores.

A question has been raised as to the best direction to give long groins—up-stream pointing, down-stream pointing, or a direction perpendicular to the current. In their report on the Yellow River, the engineers[10] employed by the League of Nations have advised groins pointing up stream. On the silty Missouri River groins pointing slightly down stream or perpendicular are preferred. Two questions seem to enter into this problem: (*a*) The rate of silting on the foreshores; and (*b*) the turbulence designed to produce the best scour of the river bed and the best silt transportation.

It appears to the writers that hydraulic laboratory experiments can do much to solve the question of groin direction. It is fairly obvious that, for various conditions, one angle will be better than another. The correct or incorrect direction may even be sufficient to determine whether or not the Yellow River, in its upper reaches (where the condition of the bed is not influenced by the extension of the delta at the coast), will raise, maintain, or lower its bed. Channel boundary conditions are important functions in determining the relation between frictional resistance and turbulence, and, as the aim must be to have the greatest turbulence with the smallest flow friction, the direction and shape of the groins may play a decided rôle in the bed scour, refill, and silt transportation questions. Although the river is wide compared to the short groins, and the general bed conditions are seemingly more influential in creating turbulence than the groins, it may be quite possible that the groins can influence the bed conditions as well, and hence, in a double sense, the turbulence. It has also been contended by writers on fluid mechanics[11] that the boundary conditions during increasing and decreasing stages of flow are extremely important, and that certain frictional boundary conditions may even cause still water or eddy flow in the boundary layers during a rapidly decreasing flow. In a silty river this explains partly, if not wholly, the rapid refill which occurs as soon as a flood period has passed its crest. That groin shape and direction can modify the refill somewhat is possible and is certainly worth investigating. Extensive hydraulic laboratory experiments to find the best solution to this problem are likely to repay themselves a hundred-fold.

---

[11] "Modern Conceptions of the Mechanics of Fluid Turbulence," by Hunter Rouse, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 463.

Influence of the Delta.—It has been stated in the "Introduction" that the steady advance of the delta into the shallow Gulf of Chihli causes a flattening of the slope of the river bed in the down-stream section of the diked course, making this higher than the plain. As far as can be estimated from the existing hydrometric records the silt volume that is being deposited on the undiked delta land, and in the neighboring sea, amounts on the average to about 15 000 000 000 cu ft per yr. Previous estimates of 8 000 000 000 to 10 000 000 000 cu ft per yr are unquestionably too low, whereas the observed silt quantity of 35 000 000 000 cu ft passing the Litsin Hydrometric Station in 1934 seems much greater than the average. In 1935 only 12 000 000 000 cu ft passed the Litsin Station; but if the Tungchuang breaches had not occurred, it would probably have been approximately 25 000 000 000 cu ft, a volume still greater than the average under the present condition of frequent dike breaches.

After the diked course has been regulated and well protected the average yearly silt volume reaching the delta and the sea may be as much as 22 000 000 000 cu ft, which means that the delta will advance faster eastward than it does to-day. It does not seem likely, however, that in the near future the river course in the lower diked section will become much more elevated above the plain than it already is. Table 1 shows that the slope from Lokou to Litsin is 1 : 12 600, from Litsin to Holungchu, 1 : 10 000, and from Holungchu to the sea, 1 : 6 000. Toward the end of the Nineteenth Century the dikes were extended from Litsin 10 miles down stream, but it was only during the present decade (1928–1938) that they were continued the next 5 miles to Holungchu. The low-water surface between Lokou and Litsin is almost uniformly 5 to 6 ft higher than the plain. At a point 10 miles down stream from Litsin it is practically level with the plain, while at Holungchu, where the dikes end, the low-water elevation is about 2 ft lower than the delta plain. This merely shows that the dikes east of Litsin have been built on the advancing steep, frontal delta débris fan. Beyond the ends of the dikes the silt spreads and deposits freely in all directions; and, as the débris fan is extended, the slope inside the diked course will be flattened to correspond with that up stream from Litsin. As long as there is distance enough for a steep, frontal débris-fan slope to exist between the ends of the diked course and the sea coast, however, it does not seem probable that the super-elevation of the diked course from Lokou to Litsin will become much greater than it is at present. Hence, the slope of 1 : 12 600 should not become markedly flatter, at least not for some time to come (see Fig. 30).

Surveys conducted by the British Admiralty about 1870, by the German Land Survey Bureau some time after 1900, and by the Chinese Hydrographic Survey Bureau and the Yellow River Commission in 1936 and 1937, show that the delta has advanced 12 miles, corresponding to a rate of one-sixth of a mile per year since the British survey was made. Since the time of the German survey the advance has been about one-fifth of a mile per year. The delta sector has a radius of approximately 40 miles, and a sector arc-length of 60 miles. The average sea depth has been approximately 40 ft, the under-water slope of the deposited material, judging from recent surveys, is about 1 : 1 500, and the frontal slope of the delta fan as it is to-day—namely 1 : 6 000. This gives a total deposition volume of approximately 1 150 000 000 000 cu ft.

Chihli Gulf Sea Floor

FIG. 30.—ADVANCE OF THE DELTA FAN AND THE GRADUAL DISAPPEARANCE OF THE STEEP FRONTAL SLOPE INTO THE SEA

Since the annual silt volume passing to the delta and the sea has been estimated at 15 000 000 000 cu ft, it has taken almost 76 yr (since about 1862) to deposit the foregoing volume. This is in fair agreement with the advance rate of the delta as given by the surveys, if allowance is made for silt carried beyond the 60-mile arc-length front. The latest Japanese maps, printed in 1935, show the average depth in the Gulf of Chihli (that part lying west of Longitude 121° E) to be about 22 to 23 m or, say, 70 ft. If there is no geosynclinal action interfering with the elevation of the sea floor, the Gulf of Chihli should become dry land (except the part north of Latitude 39° N) within 2 000 yr, assuming that the Yellow River continues to flow into it and has the same silt-carrying capacity as at present. This is an interesting speculation; but what is of more importance is to decide if there is any immediate cause for alarm due to the rapid delta advance. The length of the steep frontal slope of the delta fan from Holungchu to the coast line is 37 miles; and, assuming a rate of advance of the delta under a regulated condition of the Yellow River to be one-fourth of a mile per year, it will take 148 yr for the delta front to have passed completely into the sea. (Actual computation on the basis of 22 000 000 000 cu ft per yr gives 138 yr.) After all, this is not a very long period, and when it has passed, a highly critical situation will rapidly develop which is likely to spell the doom of the present course from the Grand Canal to the sea. Hence, it is important that the advance of the delta should be retarded as far as this is possible. One way would be to try to distribute the silt over a longer front than at present.

The length of the coast line along which the river has spread its silt during the last 70 yr has been stated to be 60 miles. It may be possible to lengthen this coast line gradually to about 100 miles by having a three-forked diversion point 10 miles below Litsin, one arm going in a northerly direction, one to the east, and the third toward the southeast. Each branch would need to be diked from the diversion point for a distance of 5 or 6 miles, the diking being continued from time to time as the delta fan advances. To prevent any of the branches from developing their sections so that the flow shall become unevenly distributed it would be necessary to construct submerged sills with bank revetment immediately below the offtake point of each branch. (An hydraulic laboratory experiment would be necessary to determine the best divergence angles of the branches to make sure also of an even silt distribution.) Dredges may be used to clear away silt from any of the branches that might tend, temporarily, to silt up. They might also be used to coax the flow with its silt to pass to the sea in as few channels as feasible in order to avoid a flooded condition in the open delta just below the ends of the diked branches. Such deposition frequently takes place to-day and causes silt settling with a rise of the river bed and increased flood stages for a considerable distance up stream from the head of the delta. When the course is good through the delta and most of the silt passes out to sea the diked course up stream again becomes deeper. If the silt can reach the sea it will be distributed better by the littoral currents, which are quite pronounced. It seems natural that the up-stream course should tend to deepen when the delta course is good since, then, there will be a tendency for the flow to scour a deeper channel in the transition zone between the steep and the flat slopes, and by back-cutting, this propels itself up stream. There are indications that this cycle of bed rise and scour, due to good and bad delta channels, influences the diked course as far up stream as the Grand Canal crossing. It is of special importance to have the delta channel in good condition before the flood season arrives as an early serious flood may cause overtopping of the dikes in the lower reaches if it should find the bed in a deteriorated condition and the scour not rapid enough to accommodate the flow. This nearly happened in 1936.

If as much of the silt as possible can be made to reach the sea, two objects are attained: (1) To prolong the life of the steep frontal delta fan slope, which prevents flatter slopes from developing up stream; and (2) to keep the up-stream channel in a deeper condition.

It does not seem technically feasible to construct training works at the mouth to guide the flow and the silt into deeper water where the littoral current could distribute it. Even with this agent acting the silt deposition would be too rapid locally. The training works would also have to be tied to a dike system extended to the coast, which, again, would mean a deposition of the entire silt volume over a limited area. This should absolutely be avoided since it would soon re-act unfavorably on the course up stream. Spreading the silt over a wide front so as to maintain the present course as long as possible seems the best plan. The one advocated is one of several that may be adopted. The Tu Hai Ho by-pass channel which has been proposed should be guided to the north of any branches that may be conducted across the delta.

If nothing is done in the loess areas of the Yellow River water-shed to diminish the soil erosion, there is certain to be serious difficulties in maintaining the Yellow River on its present course from the Grand Canal to the sea after another two centuries have passed. During the next few decades every effort should be made, therefore, to enforce an energetic soil-erosion control campaign. This promises so much for the Yellow River that no statements recommending it can be too strong.

Control of Soil Erosion.—Were it not for the heavy load of silt in the Yellow River at high stages, the flood-control problem would be far less difficult. The vast quantities of fine loess soil that are washed off the hillsides in Kansu, Shensi, and Shansi, in the rainy season, and are brought into the Yellow River by such feeders as the Wei Ho, the Lo Ho, and the Fen Ho, create a most formidable problem. Therefore, erosion control should be a most important factor in flood control for this river; and, yet, there is ample evidence that it has not been practiced in a sufficiently effective manner. It is true that many farmers have sought to protect their side-hill lands by terracing them and have done so to a degree. However, the thousands of gullies and ravines that have been cut into these loess hills by the agency of running water bear testimony to the wearing away of these lands at an alarming rate.

In his soil studies in China Mr. James Thorp has called attention to this problem,[12] and states that the methods of control adopted by Chinese farmers have been only partly effective, although he finds the terracing in Northwest China to have been conducted over a wide area. Lack of rock supply and timber reasonably close to the regions being treated has made this work less effective in the great loess-covered water-shed of Kansu and Shensi, for example, than in the hilly parts of Shantung where stone walls are used in making lasting terraces. More rigid application of rules as to level terraces, contour plowing, and pit and strip planting, as well as suitable supervision of a drainage system, will all aid in preventing further inroads of eroding processes on the lands that are now used for cultivation. However, in the great problem of controlling the gullies and ravines that are already deeply cut into the landscape, timber and stone must be used in broad areas where these are very difficult to obtain. Here, the power of the State must enter and a large subsidy must be created to aid local farming communities to put these gullies and ravines under control if this erosion is to be seriously and effectively retarded. The native population does not possess the wealth or the leadership to carry through this phase of the program, which will be costly and will require at least two or three decades with Government support of a most substantial character. If the outside support is only moderate, a century or more may pass before this important part of the Yellow River flood control is well in hand.[13]

The field laboratory, established in Western Honan early in 1937 to make certain experiments in connection with gully-erosion control, has yielded few results. Those in charge made certain brief field studies in Japan and, later, were driven from their work by war conditions. The only laboratory work of significance to date in this connection is the great natural open labora-

tory of the Chinese farming community extending throughout the loess-covered areas. The observations of the writers over many years lead them to believe that the condition of these gullies, many of which will lend themselves readily to treatment by a series of low earth dams supported by cribwork or piling, can be improved within one generation at reasonable cost under intelligent leadership where a way is found to obtain the general co-operation of the various land-owners and strong State support.

Reforestation and Run-Off.—It has long been the hope of students of North China's flood problems that some method might be found whereby the rainfall that is concentrated almost entirely in the months of July, August, and September, with occasional heavy rains in late June, might be spread out over a longer period, or that the run-off might be better distributed through the year. Since storage of flood-waters in reservoirs for weeks or months is not practicable for the Yellow River system, due to the heavy silt content in the water during the rainy season, the remedy of reforestation has been frequently recommended as a panacea.

The speculation that has existed in China as to the effect of extended reforestation on run-off in the Northwest has not produced a unanimous opinion among climatologists as to the possibility of prolonging the rainy season. The group that has insisted for the past two decades that China's flood problems will be remedied, to a great extent, by heavy reforestation in the arid regions of the Northwest, has gradually become less vocal as the difficulty of the problem has been shown, and as more has been published on the matter of storm occurrences due to cyclonic action. To the writers it appears that, although the duration of the rainy season may not be appreciably increased and the climate modified by forests in a way to produce more frequent rains, there may be a distinct benefit in the line of arrested run-off if North and Northwest China ever developed a suitable forest cover. Such a cover over one-half the area of Kansu, Shansi, and Shensi, cannot be obtained at any reasonable cost and will require several decades of persistent effort due to the dryness of the climate and poverty of the country.

For many centuries seasonal typhoons have been coming in from the regions in the Pacific Ocean east of the Philippines and drifting westward to the China coast and then north through China. Other storms belong to the continental system originating in West-Central Asia and drifting eastward, as discussed heretofore in this paper. These typhoons are all of such force as to be only little affected by such forest cover as may develop in the Northwest Provinces.

RIVER UTILIZATION

Power Development at Hu-kou Falls.—Only since about 1933 have serious studies been made of power development on the main course of the Yellow River. Difficulties with storage on account of the rapid silting of reservoirs have made impracticable any large power developments on the main tributaries, such as the Wei Ho in Shensi, or even the Fen Ho in Shansi, although in either case winter flow, with its low silt load, may be stored a few months for spring irrigation. The Yellow River, however, has a sustained low-water flow at Hu-kou Falls warranting hydro-electric development at that point, whereas along the gorges of the Yangtze, no great industrial city is near-by to use the power thus developed; but the possibility of utilizing power for pumping in connection with irrigation in Southwest Shansi, as well as for industrial uses in surrounding *hsien* cities (a "*hsien* city" is a "county-seat"), seems to warrant the development of the power afforded by this fall in the main river.

The Hu-kou Falls are 125 miles north of Tungkuan, Shensi, or nearly 45 miles north of Yumenkou. After having passed a series of rapids and narrow gorges between Hu-kou and Yumenkou (see Figs. 31 and 32) the river debouches on a plain which lies chiefly in Eastern Shensi, but also includes the valley at the mouth of the Fen Ho, in Shansi. The region to the east of the river, from the Fen Ho south, is a loess plateau of which more than 150 000 acres lie on an average of 250 ft above the river at Yumenkou. This land might be irrigated by pumping from the Yellow River, using low-priced power from Hu-kou Falls. The climate and soil are both well adapted for cotton growing.

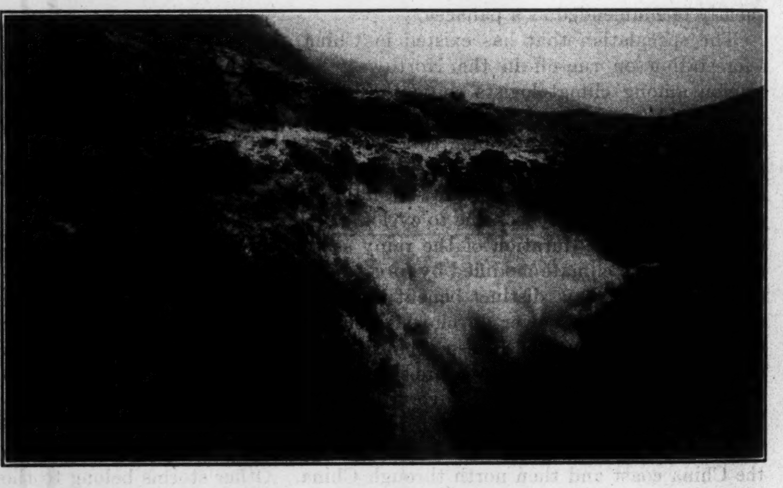

Fig. 33.—Hu-kou Falls on the Yellow River

In 1934, surveys, studies, and geological investigations were made of the Hu-kou site under the direction of one of the writers. Estimates based on these and other investigations indicate that a development of 100 000 hp dependable every day of the year can be made very economically, costing approximately $3 000 000 in United States currency, including transmission to Yumenkou and vicinity. With a diversion dam 40 ft above the river bed and 600 ft up stream from the Falls (Fig. 33) the available head at the power site, chosen 5 000 ft down stream, would be a little more than 110 ft. If a flood-control detention basin is to be established above these Falls, the problem of combining such flood-control project with the hydro-electric power development remains to be considered. Probably it can be solved by letting the lower 40 ft of the dam act permanently as head for power while the higher dam section will serve for flood-control purposes.

Irrigation.—A thorough program of control for the Yellow River will include improvements to existing gravity irrigation projects, such as those near Ninghsia, the Ho Tao region, and Saratsi. In addition to them, however, two projects already mentioned might be undertaken that would require pumping on to table-lands in Southwest Shansi, immediately south and east of Yumenkou. One of these projects, near Hotsin, was surveyed in 1934 under the direction of one of the writers, and its construction has been strongly urged by the local officials. In embraces 50 000 acres of cotton land on terraces and sloping plains from 200 to 300 ft above the Yellow River at Yumenkou. A larger tract lies across the Fen Ho to the south of Hotsin on a plateau, where approximately 200 000 acres, lying at an average elevation of 250 ft above the low-water stage of the Yellow River (where the Fen Ho meets it), offers irrigation possibilities. As yet (1938) no reliable surveys of this area have been made. This land is particularly adapted to cotton growing, but it frequently suffers from deficient rainfall. Development of cheap hydro-electric power at Hu-kou would make the building of an irrigation system practicable.

Ten miles above the Peiping-Hankow Railway the Yellow River might be tapped on the north bank for a gravity irrigation project that would parallel the river to the east. Although surveys have not been made for laying out canals for such a project, studies of available maps indicate that an area of at least 200 000 acres may be irrigated at a reasonable cost. This irrigation would insure crops of cotton, beans, wheat, etc., in drought years. Most of the land that would be served thus is of good quality for mixed agriculture and can maintain a farming population of 1 000 per sq mile.

An indispensable accessory to all irrigation plans for the Yellow River in the plain is that the river channel must first be stabilized where it runs past the intake works. If not, the river is certain, after a few years, to form a high foreshore in front of the intake due to silt deposition and change of course.

Fertilization by Flooding.—The dike break of 1935 in Western Shantung carried large quantities of fine sand out of the river bed across country to the southeast. Inspection trips over this flooded region were made by one of the writers both in June and in October, 1936, to estimate the damages and the benefits due to sand and good silt deposits. The heaviest sand deposit followed the course of the principal channel eroded by the flood waters for a distance of nearly 50 miles making almost worthless for agriculture approximately 350 sq miles of farming country that, in previous floods, had sustained similar injury, but had again been improved by fertilization and farming. The October inspection trip showed that the late spring planting on these lands yielded scarcely enough to pay for the seed. Farther away from the break where there had been ponding with but little current, deposits of very fine silt or loess had greatly improved the land. Over large areas 50 to 60 miles from the break such deposits of clay-like silt were from 1 to 2 ft in depth, but not, as a rule, dry enough for planting in 1936.

It seems probable that systematic flooding of these low, sandy lands by the use of adequate gate structures, that will retain most of the sand within the river bed while accumulating a deposit of fertile silt over the area, will prove feasible and beneficial. A zoning plan can be developed so that each year a district on each side of the river may benefit by such controlled flooding. Five or six years later those same areas would have another turn to receive fertile mud from the river through controlled flooding at times when the suspended silt load is high.

Attempts have already been made in Eastern Shantung to siphon Yellow River water on to alkali lands near the sea; but even with the 24-in. cast-iron pipes thus used the process is slow. Flooding through an extensive system of gates seems necessary if this land improvement is to be undertaken seriously.

Navigation Improvements.—At present, only light-draft junks can ply the Yellow River in the low-water season. A power launch drawing more than 2 ft would have difficulty navigating the diked section of the river in low-water stages. With the proposed training of the channel, perhaps, depths slightly exceeding 3 ft may be maintained at all stages, although bars will continue to be built in new places as the bed-load moves and new silt deposits are laid down. This applies to the river from the Peiping-Hankow Railway to the sea. In order to have depths greater than 3 ft it would be necessary to construct a system of contraction works inside the proposed regulated channel. This would interfere with the river's scour action, however, and would prevent the enlargement of the channel so necessary for carrying the flood flow safely. Perhaps it would also encourage increased refill which would cause the bed to rise more quickly than otherwise. The only navigation improvement worth while would seem to be a light system of construction works at places which show tendencies to much shoaling. These works would be washed out by the first freshets and would have to be replaced early each spring. Of course, the deepest channel would have to be marked constantly.

From the Peiping-Hankow Railway to Tungkuan, the country on both sides is mostly very mountainous and sparsely populated. The currents are swift on account of the river's steep slope, making up-stream navigation slow and difficult. The treacherous Sanmen Rapids are also much feared by the boatmen. Before the construction of the Lunghai Railway this part of the river carried a large part of the exports from Southeast Kansu, West Shansi, and Central Shensi; but the railway has now practically absorbed all the traffic and there is left only a small tonnage of coal transportation from mines along the banks below the Sanmen Rapids. Navigation through this section is now unimportant and not worth considering.

From Tungkuan to Yumenkou no very swift-water stretches are encountered, but immediately to the north of Yumenkou there are gorges where the river is very narrow, and the rock walls are nearly vertical in many places (see Fig. 31). Above Yumenkou there are a number of important coal mines from which the Lunghai Railway and large areas in Central Shensi draw their coal supplies. At high-flood stages no craft can go up these gorges and, even in low water, the coal barges have difficulty in getting through the 15-mile stretch from Yumenkou to the coal mines above the gorges. Good power boats may be feasible here as the traffic seems to warrant their use.

For the next 30 miles to Hu-kou Falls the river has a number of rapids. Boats rarely go up this stretch, therefore, although they may shoot these rapids on their way down stream after being hauled around the Falls. In consequence, only cheaply constructed shells are made for traffic through this section and such boats are sold in Honan or Shantung as it is not economical to make the return trip

The question of getting boats around the Hu-kou Falls has been a problem for years. The passage is highly dangerous except for a short season of the year when unloaded cotton boats may be taken down a small channel prepared for that purpose. All cargo is carried past the Falls by donkeys, a distance of two miles, and then reloaded. As yet the construction of modern locks to handle boat traffic past these Falls has not been seriously discussed by the authorities.

Other rapids 200 miles farther north make navigation of this part of the river dangerous in low water. Sharp rocks often tear holes in boats that attempt to pass down this section. Pilots must use the greatest caution and pick a medium stage of river for travel.

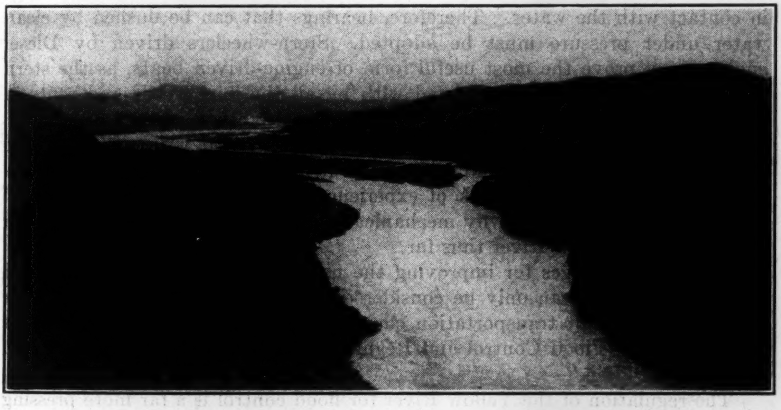

FIG. 34.—THE YELLOW RIVER 20 MILES BELOW LANCHOW, KANSU, 1931

Although Shansi officials have discussed improvements to navigation, so that grain boats may go from Ninghsia and Suiyuan to points in their own Province, the regulation of the Yellow River along the west border of Shansi has appeared too formidable and has not been undertaken. The problem is worthy of further study, since water transport may prove cheaper than rail haulage if it can be handled safely and without costly portages. It would not be an all-year service due to the long ice period and the suddenly appearing freshets of the high-water season, but it might be relied upon for six months of the year.

An interesting form of navigation exists between Lanchow and Paotou. In the spring, the natives at Lanchow construct rafts of ox hides stuffed tightly with wool or sheep skins, inflated with air, and lashed to a top framework of light wooden poles. As many as 120 ox hides, or 500 sheep skins, are used for each raft. It is down-stream navigation only, but as much as 20 tons of goods have been carried on a single raft. The passage through the narrow, jagged gorges between Lanchow and the Ninghsia border is rather perilous (see Fig. 34) and many rafts have been wrecked in this stretch; but the overland journey to the coast is so long and expensive that the dangers of the river route are risked. On arrival at Paotou the wooden frame is sold and the skins deflated and carried overland back to Lanchow. Two trips per year are all that can be made by one crew.

Boats are also used on the stretch from Paotou to the Kansu-Ninghsia border for down-stream as well as up-stream navigation, but they cannot ascend the gorge section to Lanchow. It is possible, but very costly, to improve the gorges so that boats may reach Lanchow. Under present trade conditions of Northwest China, however, such heavy expenditures are not warranted.

Steam or motor-driven launches which have been tested on the Yellow River have always encountered trouble because the silt wore out all bearings in contact with the water. Therefore, bearings that can be flushed by clean water under pressure must be adopted. Stern-wheelers driven by Diesel engines may prove the most useful form of engine-driven boats, as the stern wheel is less likely to be interfered with by all the long weeds and roots in the water during floods. The axle-bearings are also above water.

A boat with an air propeller has recently been tried with some measure of success between Paotou and Ninghsia; but maintenance trouble has been a drawback. It seems that lack of experience with engines and their upkeep has been the main reason why mechanically propelled crafts have not been a success on the Yellow River thus far.

The use of dredges for improving the navigable channel along the diked course of the river can only be considered in connection with maintaining a better flood and silt transportation channel as mentioned toward the end of the section on "Flood Control and Regulation: Regulation of Diked Channel Through the Plain."

The regulation of the Yellow River for flood control is a far more pressing problem than putting this river into condition for safe navigation. In fact, the former must precede the latter.

Magnitude of a Comprehensive Program

The area lying within the Great Plain where floods have done so much damage during recorded history, and where, at any time in the future, the population may suffer if adequate control and regulation work is not undertaken, is estimated to have an area greater than 35 000 000 acres, or 55 000 sq miles—approximately the area of the entire Shantung Province (see Fig. 35). The Provinces of Hopei, Honan, Kiangsu, and Anhwei, as well as Shantung, all have plain lands subject to damage by these floods. Parts of all these

Provinces might well bear a moderate annual flood protection tax of 20 cents (U. S.) per acre for a period of two decades or more. If this is done the Central Government will be better able to lend aid to the poorer Provinces of Shansi, Shensi, and Kansu in coping with the soil-erosion problem, which will require three decades or more of persistent work to solve in a satisfactory manner.

Fig. 35.—Approximate Areas Threatened by Yellow River Floods

Since construction costs in China are far less than those in America the necessary work can be done very reasonably, and Yellow River floods, such as have cursed North China in the past, can be made so highly improbable in the future as to be no longer dreaded by the people who live within their reach. The Great Plain of China can be made a perfectly safe place in which to dwell. Furthermore, it can be improved in a number of ways aside from mere flood protection. The follow-up work of soil-erosion control, in the Shensi and Kansu water-sheds particularly, will be possible with continued National Government encouragement; but it is time to begin this problem in earnest. The struggle against these floods has gone on throughout China's history. The means adopted to combat them have only partly solved the problem and then only for very limited periods. Far better insurance is necessary.

ACKNOWLEDGMENTS

The writers desire to acknowledge the assistance of C. N. Joyner, M. Am. Soc. C. E., Deputy Municipal Engineer, British Municipal Council, Tientsin, China, and Dr. Erik Nystrom, Professor of Geology, Shansi University, for their reading of the manuscript and their helpful criticisms and suggestions in connection with the text. Sincere acknowledgment is given also to the Hon. Charles R. Crane, former United States Minister to China. His intense interest in these engineering problems and his continuous support have made possible not only the extensive studies involved, but their publication for the benefit of Americans and Chinese engineers alike.

DISCUSSION

J. W. **Beardsley**,[14] M. Am. Soc. C. E. (by letter).—Exceptionally detailed and comprehensive data on a difficult problem are presented in this paper. To appreciate the work involved one must consider the Chinese language which is not adapted to technical terms, the lack of co-operation between adjacent provincial authorities during past centuries, and the failure of the National Government to collect data and to plan and construct protective works.

During 1918–1920, the Grand Canal Improvement Board collected samples of silt in the vicinity of Shihlipu and the railroad crossing near Tsinan Fu by means of a hand pump and a pipe which could be lowered to any desired depth. A silt load of 15% by weight was rather high. Samples were also collected from old silt beds and measured carefully. It was concluded that 15% by weight averaged close to 10% by volume. Recently deposited silt beds, sun dried, were cracked into irregular blocks about 2 or 3 ft wide and 3 or 4 ft long. The cracks were 1 ft to 2 ft deep. Along the edge of such banks, where the current had been relatively swift, were generally found small areas of fine sand suitable for use in an hour-glass. Probably such sand would be harmful to soil fertility, whereas the average run of the silt would be beneficial.

The deltaic central plains are said to have been very fertile many years ago; but the intense cultivation during past decades has materially reduced fertility. Missionaries reported that their census of areas adjacent to Tsining, on the Grand Canal in southwestern Shantung, gave a population of about 2 000 per sq mile. A food crop is a prime necessity. The farmers live mainly in the protected villages. A common type of irrigation in this area is by water drawn from wells which have a stone post on each side suitable for using a windlass. The farmer carries the windlass and bucket from the village, adjusts the windlass in the stone posts, draws a bucket of water, and carries it to his small cultivated plat.

This part of China has no "April showers to bring May flowers." It has slight snowfall or rain during the spring. Soil moisture is not sufficient to sprout early plantings. The later seasonal rains usually interfere with the harvest.

Data are not available relative to the decreasing fertility of these deltaic areas. Sir William Willcoks referring to the displacement of "basin" irrigation in Egypt by the then new perennial irrigation said:[15] "The rich muddy water of the Nile has been the mainstay of Egypt for many generations, it can no more be dispensed with today than it could be in the past."

The Nile and the Yellow rivers have many similarities. Both are deltaic rivers. Both lack tributaries of any importance several hundreds of miles above their mouths. Both have built up silt banks higher than adjacent lands. A notable dissimilarity is that the Nile has been orderly. It is the life of Egypt. The Yellow River is an unruly bandit to such an extent that it is called "China's sorrow."

---

[14] Cons. Engr., Syracuse, N. Y.

[15] "The White Nile and The Cotton Crop (No. 2)," by Sir William Willcoks; a lecture delivered at a meeting of the Khedivial Geographical Society, January 25, 1908.

The authors' discussion of "Irrigation" and "Fertilization by Flooding" are exceptionally interesting. Similar comments on reclamation would have been of equal interest. With considerable hesitation, the writer ventures to make two suggestions for making a useful servant, at least a part of the time, out of the unruly Yellow River:

(1) Adjacent to the river's old bed prior to 1851 (and in several other localities near its present bed) are a number of shallow lakes and marshy areas too wet for cultivation. Is it practicable to fill such areas with the July floods? The silt loads in the vicinity of the Peiping-Hankow Railway Bridge frequently carry 15% or more of silt by weight, or 10% by volume when compacted. An impounded basin having a maximum depth of 5 ft would deposit a half foot of soil within a few days. Within a few years such areas could be converted into "culturable" land.

Non-fertile sandy areas could be made productive by impounding a depth of a few feet of flood waters, heavy with silt, for two or three days before draining. If such an operation could be repeated annually for a few years, high fertility would be maintained for many following years.

(2) Is it practicable to flood those areas near the river, where irrigation is difficult, with the low-water flow of late winter or early spring? Some soils take up moisture slowly and the retention of the water might be necessary for a week or more before sufficient moisture is absorbed to sprout early plantings. The basin must then be drained and the retained moisture should be sufficient to carry the crop until the arrival of the summer rains.

The silt load is then generally about 1 per cent. If a depth of 2 ft were impounded, the silt deposited would be of considerable value as a fertilizer, especially if the operation can be repeated each year. This plan conforms to the "basin" irrigation of ancient Egypt.

As long as a stable government control is disturbed and co-operative maintenance of the system of dikes remains impracticable, the danger that the Yellow River will usurp an unpredictable channel to the sea is increased manyfold. Sooner or later these river problems must be solved.

ELLIOTT J. DENT,[16] M. AM. SOC. C. E. (by letter).—This paper is an extremely interesting one as it places before the profession many facts that have not, heretofore, been available with respect to this extraordinary river. "China's Sorrow" is such an unusual stream, and the local conditions are so at variance with those that river engineers are accustomed to find elsewhere, that the description has many of the intriguing qualities of a Jules Verne novel. The quantities of sediment shown as passing the hydrometric station at Chinchang are so great that there should be outstanding evidences of buried structures throughout the alluvial plain, and Mr. Thorp has mentioned the case of a pavement buried to a depth of about 12 ft at Kaifeng, a few miles west of the 1851 break. The authors state that there is reason to believe that the serious erosion now taking place in Northwest China began at about the time of the Emperor Yü (2200 B. C.) but, even so, the depths of deposit in a period of 4 000 yr should have attracted more attention than is evidenced by the mention of a single case by Mr. Thorp.

---

[16] Col., U. S. Army (*Retired*), Washington, D. C.

Although the writer confesses a certain degree of skepticism with respect to the capacity of a river to carry sedimentary loads of the magnitude reported, the data have been accepted, for the sake of discussion, and an effort has been made to indicate some of the inevitable consequences that must follow from such a condition.

The slope of a river is one of its most important characteristics, and a profile is very useful in studying its habits. In Table 1 the authors give the necessary data and Fig. 36 has been prepared to show the slope from Shanchow (Mile 624) to the mouth. All elevations are referred to Taku Datum, the zero of which is 4.5 ft below mean sea level. As should be expected, when dealing with a stream as unstable as this one, the distances shown are somewhat different from those used by Mr. Freeman.[3] A number of stations not included in Table 1 have been approximately located by reference to the text or by scaling the distance to the nearest known point.

Shanchow, Mile 624, to Chinchang, Mile 441.—Between Shanchow and Mengtsin, Mile 503, the river flows through the last of its mountain gorges with numerous rock ledges and minor rapids; in this section it is an eroding stream carrying an enormous load of loess in suspension. A short distance above Mengtsin it enters its area of deposition and begins to meander from side to side of an alluvial valley in a bed composed of sandy material dropped by the river itself. A short distance above Chinchang (site of the Peiping-Hankow Railway Bridge) two tributaries, the Lo Ho and Chin Ho, enter the main stream. The importance of these branches as flood carriers was illustrated in 1935, when they added about 300 000 cu ft per sec to the July flood of that year. These tributaries drain an area covered largely by Tertiary deposits of red clay, and they do not carry as much sediment as the main stream at Shanchow. Moreover, the clay is finer than the loess and more easily transported. There are some strata of sand and gravel outcropping in the clay cliffs and these should add to the bed-load of the river. Certain maps, not published in the paper, indicate that the lower portion of the flood plain of the Chin Ho has been modified by a rise in the bed of the Yellow River.

In the rocky gorge above Mengtsin the average slope is about 4.6 ft per mile; and, in the alluvial section from Mengtsin to Chinchang, it is about 1.37 ft per mile. Throughout this alluvial section the bed is sandy and the river shifts from side to side of the flood plain; for the full length along the right bank the plain is bordered by the clay or loess hills; but on the left bank the dikes extend about 15 miles above Chinchang.

There is abundant evidence that the river is depositing huge quantities of sediment in the overflowed areas. The outflow from this section is measured at Chinchang and the portion of the inflow that passes Shanchow is also measured. No direct information is given with regard to the inflow from the Lo Ho and Chin Ho, and minor tributaries, but there is some indirect evidence that this amounts to several hundred million cubic yards per year.

Table 7 shows the monthly flow of sediment at Shanchow and at Chinchang for the years 1934–1935. During July, 1935, there was a flood in the tributaries amounting to more than 300 000 cu ft per sec, and during that month the outflow of sediment amounted to the inflow from above Shanchow, plus 158 000 000 cu yd. (For convenience in visualizing the extent of the flood-plain deposits it is well to recall that 1 000 000 cu yd may be taken, with an error of only 3%, as the volume of sediment required to bury 1 sq mile to a depth of 1 ft.) If, as seems probable, there were deposits during that month, the inflow from the tributaries must have been 158 000 000 cu yd plus the quantities deposited. During the 2-yr period there were nine other months in which the outflow was greater than the inflow from above Shanchow, the aggregate excess for the entire ten months having been 406 000 000 cu yd. During these ten months the inflow of sediment from the tributaries was apparently 406 000 000 cu yd plus an indeterminate volume of deposits.

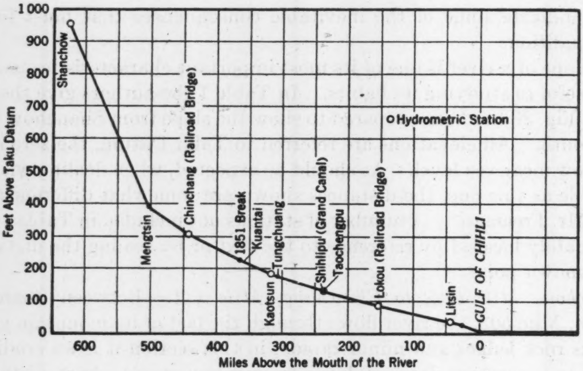

FIG. 36.—LOW-WATER PROFILE OF THE YELLOW RIVER

During the remaining fourteen months of the record the inflow of sediment from above Shanchow, alone, exceeded the outflow at Chinchang by 323 000 000 cu yd, and the deposits included this volume plus the entire inflow from the tributaries. The limited information available indicates that, for the years 1934–1935, the deposits on the overflowed land above Chinchang amounted to the huge total of more than 500 000 000 cu yd. For the flood plain below Chinchang, better information is, fortunately, available.

Chinchang, Mile 441, to Tungchuang, Mile 307.—The flow at Tungchuang will be assumed to be the same as at the hydrometric station at Kaotsun, a few miles up stream (see Fig. 29).

Throughout this 134-mile reach, the river flows along the back-bone of a ridge formed by the deposit of part of the sedimentary load. There are no tributaries; on the contrary, there is a continuous threat that a crevasse will form, permitting the wastage of part of the flood waters over the adjacent plain. In this section of the Yellow River the slope averages 0.94 ft per mile; the distance between dikes averages about 6 miles; the channel is constantly shifting its position between the dikes and there are many sandy islands and bars; there is a heavy bed-load; there are extensive sand deposits on the foreshores and on the adjacent plain; and, as shown by Mr. Freeman[5] all of the major changes in the course of the river have originated in this section.

At Mile 365 the great break of 1851 occurred and changed the course of the river from its former southeasterly direction to the Yellow Sea, to its present northeasterly course to the Gulf of Chihli. Mr. Freeman has presented a cross-section[17] about five miles above this break which shows that the dikes were about 6.25 miles apart; that the foreshores between the dikes and the channel had been built to a level about 30 ft above the adjacent plain; and that following the break the river had eroded deep into the deposits. In 1937, as explained by the authors, the foreshore lands, for a distance of about 25 miles above the site of the break, were still above the level of the highest floods. The river bed at this point is said to be rising at a rate of about 3 ft per century, but exact figures are not given. Down stream from the site of the break, toward Tungchuang, the natural and artificial levees have not yet developed to dimensions that may be considered reasonably secure. In the great flood of 1933 there were 35 breaks in a distance of 48 miles; in 1934 there was a break at Kuantai, only a few miles below the site of the 1851 break; and, in 1935 there was a break near Tungchuang, the lower end of the reach.

Table 8 shows that the quantity of sediment passing Chinchang during 1934 was 1 915 000 000 cu yd, and that only 1 168 000 000 cu yd passed Kaotsun; the difference, 747 000 000 cu yd, was deposited between the dikes or spread over the plain as a result of the Kuantai break. In 1935 the silt passing Chinchang amounted to 1 727 000 000 cu yd, of which 1 046 000 000 cu yd passed Kaotsun; the difference, 681 000 000 cu yd, was deposited between the dikes. In 1935 a considerable part of the sediment that had passed Kaotsun was subsequently spread over the plain as a result of the crevasse at Tungchuang.

The profile of the river, the location of the various outlets since the beginning of the historical record, the descriptions of the shifting channels and numerous sand bars and islands in the upper reaches, the references to the relatively better defined channels in the lower reaches, the descriptions of the sand and gravel strata in the eroding Tertiary cliffs, the references to the bed-load and to the sand deposits on the foreshores and adjacent plain above the 1851 break, the data with respect to the silt loads at the various hydrometric stations, and the reports that the bed is rising—all of this evidence is in accord as pointing to the conclusion that the alluvial plain from Mengtsin to Tungchuang is now serving as a settling basin in which the coarsest part of the sedimentary load is deposited. The record of silt observations at the hydrometric stations and the statement that the river bed at the site of the 1851 break is rising at the rate of about 3 ft per century are in agreement as indicating that sediment is being deposited, but in notable disagreement as to the rate of such deposit.

The foregoing deductions should be checked by additional field surveys, and these should include mechanical analyses of the sedimentary deposits throughout the flood plain. Similar analyses should be made of the suspended load at each of the hydrometric stations; the sedimentary load should also be measured at one of the minor rapids above Mengtsin where the entire load will presumably be in suspension and therefore susceptible to being measured. The gage records at the Lokou (Mile 152) and Chinchang railroad bridges should be examined to see whether the low-water levels at those points are changing; and all available information with respect to changes in elevation of the river bed, the foreshores, or the adjacent plain should be assembled and studied.

---

[17] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), Fig. 12, p. 1421.

Tungchuang, Mile 307, to Litsin, Mile 42.—The hydrometric station nearest to the mouth is at Litsin and the 265-mile reach from Tungchuang to that point will be considered as a unit. The Grand Canal crosses the river at Shihlipu (Mile 236) and, under certain conditions, water that has escaped through crevasses above that crossing is returned to the river at that point, after having been nearly completely clarified by sedimentation. From Tungchuang to the crossing the average distance between dikes is about 4 miles; below the canal the width is about 1.25 miles. Below the crossing the channel is more clearly defined than above that point. The average slope for the entire 265-mile reach is 0.54 ft per mile.

Table 8 shows that in 1934 the volume of silt entering the reach was 1 168 000 000 cu yd and the volume leaving at Litsin was 1 295 000 000 cu yd. In 1935 the crevasse near Tungchuang allowed the escape of an unknown, but very large, volume of water and sediment. The hydrometric station at Taochengpu, about Mile 236, showed an annual load of 514 000 000 cu yd as compared with 447 000 000 cu yd at Litsin. These values are not conclusive proof of either fill or scour between the dikes of this reach during the 2-yr period.

Delta.—In the discussion of plans for the control of the Yellow River, the authors state that the sediment to be discharged at the mouth may be as much as 815 000 000 cu yd per yr, a value far less than the quantity shown as having entered the diked channel at Chinchang during 1934 and 1935. Their discussion of the rate of advance of the delta into the Gulf of Chihli indicates that no insuperable problem will be encountered at that point during the next century, but that very serious difficulties may arise within the next two centuries.

General.—When a project is under consideration for the control of a river flowing in an alluvial bed, between natural or artificial levees, the thought is often expressed that the stream should be so guided and controlled that the entire sedimentary load will be carried from the head of the valley to the sea without the deposition of any part en route. Assuming, without demonstration, that this can be accomplished in the flat sections near the mouth, the proponents then look at the steeper slopes in the upper reaches of the area of deposition and propose, further, that the same methods of control be applied to the reaches of relatively steep slope. They argue that this should cause erosion and that the river should cut its channel deep into the friable deposits, and thus lower the high-water surface to a level below that of the surrounding plain.

The Emperor Yü (2200 B.C.) is alleged to have controlled the Yellow River by causing the flood waters to flow to the sea at levels below those of the surrounding plain. Unfortunately for humanity, this tradition must be classed as a myth or the method used 4 000 yr ago must be cataloged as one of the lost arts. In recent years, when it is proposed to make the Yellow River dig deep, the method advocated calls for a reduction in width and a debate starts as to whether this contraction will result in a lowering of the bed or whether it will cause it to rise at a faster rate than at present. Those claiming that the bed will be lowered base their arguments on the higher velocities that will be found in the narrowed channels, and the observed scour that has been noted in certain short reaches where the channel now has the width proposed. Those believing that the bed will be raised hold to the opinion that the highest velocities obtainable in practice will be lower than those necessary to carry the entire sedimentary load to the sea, and that the reduction in the area over which the deposits will be laid down will increase the depth of the annual accretions.

In nature, an alluvial river carrying a heavy bottom load builds for itself a wide bed with a slope sufficient to create an adequate bottom velocity. In discussing the effect of structures designed to reduce the width of such a stream, the increase in depth and consequent increase in mean velocity is habitually stressed. There are other factors of equal importance, however, although frequently they are left unmentioned. Exact data are not always available and, for a mental picture of the case, it may at times be advisable to depart from strictly scientific accuracy and resort to the use of rough estimates that can, at least approximately, be checked by field observation.

From the surface to within about 1 ft of the bottom, the suspended load and velocity of the river current can be measured with reasonable precision; by extrapolation the figures for a point 0.5 ft above the bottom can be closely approximated. For purposes of discussion the velocity 0.5 ft above the bottom will be used as one of the indices. At a point about 0.2 ft above the bottom, or possibly less, a movement of sand by the saltation process comes into action, the character of the load is greatly altered, the load is much increased, and the velocity of the water is reduced. No practicable method of measuring the velocity of the water and the extent of the sand movement within 0.2 ft of the bottom has been devised.

The sand, traveling by saltation, together with the much smaller quantity that moves by rolling or sliding, will be referred to as the bed-load. In the absence of information as to the magnitude of this load in the Yellow River, a very rough estimate will be made in the hope that it will be better than nothing. Based on experiments by the late Grove Karl Gilbert,[18] the bed-load in the Yellow River when the mean velocity is 5 ft per sec, and the velocity 0.5 ft above the bottom is 3.0 ft per sec, will be assumed to be 300 grams per sec per ft width of channel; this is equivalent to 20 cu yd per day per ft of width.

If the depth of a stream is 10 ft, its mean velocity 5 ft per sec, the suspended load 6%, and if 1 cu yd of deposit weighs 2 800 lb, the suspended load per 1 ft of width will amount to 5 800 cu yd per day. These rough estimates indicate that if one-third of 1% of the suspended load in the gorge above Mengtsin consists of sand too coarse to be carried in suspension through the alluvial channel, the capacity of the river to carry bed-load may be fully taxed. The profile of the river and the descriptions of its characteristics indicate that its bed-load capacity is over-taxed. (On the Missouri and Colorado rivers in the United States, a rough rule is that sand too coarse to pass through a 200-mesh sieve will be actual or potential bed-load material. The slope of the Colorado River is about 1.5 ft per mile, and that of the Missouri River about 0.8 ft per mile. Mr. Freeman stated[3] that more than 99% of the Yellow River sediment would pass through a 200-mesh sieve.)

---

[18] "The Transportation of Débris by Running Water," *Professional Paper No. 86*, U. S. Geological Survey, 1914.

It is not easy for a river carrying a heavy bed-load to dig vertically downward. As an alluvial plain is built up the natural process tends to pave the bed with the coarsest material available; any subsequent attempt to dig vertically downward results in the formation of a more and more resistant surface. On the other hand, the natural levees are composed of material carried in suspension until the velocities along the foreshores have sufficiently slackened to permit its deposit, the coarsest part of the suspended load being normally deposited nearest to the channel. These bank deposits are conspicuously lacking in cohesive qualities and are very vulnerable to attack by undermining or sapping. In expanding in a lateral direction the current need only loosen part of the material to be excavated; the remainder is loosened by the caving process. Material lifted from the bottom by the current is so coarse that much of it must be carried away by the slow process of bed traction, whereas material loosened from the banks, for the greater part, can be borne away readily in suspension. When a river must enlarge its section by excavation it is often easier for it to accomplish its purpose by digging laterally than by digging vertically downward.

If q is the bed-load capacity of a river per 1-ft width and B is the width in feet, $q\,B$ is the bed-load capacity of the entire stream. The unit capacity, q, can be increased by an increase in velocity, and this in turn can be secured by a reduction in width. However, if the reduction in width is at a faster rate than the increase in unit capacity, the bed-load capacity of the entire river will be reduced instead of increased.

The foregoing considerations create a doubt as to whether it would be possible to increase the bed-load capacity of the Yellow River by reducing its width, or that it would be possible to induce the stream to dig vertically downward to a measurable extent; but if these objectives could be attained, the present flattening of the river as it flows downward through its alluvial section would introduce further difficulties. From Mengtsin to Chinchang, a distance of 62 miles, the present slope averages 1.37 ft per mile, and the Yellow River is unable, nevertheless, to carry its full sedimentary burden through that reach. If the use of contraction works and revetments were to make it possible for the stream to carry its full load through the aforementioned section, the problem would arise as to how the stream could be trained to carry this load, larger than the present one, through the next reach to Tungchuang, a distance of 134 miles, with a present slope of 0.94 ft per mile. If the problems of both of the aforementioned sections were solved there would remain the task of training the river to carry this full load through the remaining 307 miles to the sea, the present slope being only 0.54 ft per mile.

In their discussion of a possible project, the authors state that the regulated channel should be competent to carry to the sea an annual load of 815 000 000 cu yd. The volume entering the diked channel at Chinchang is stated as 1 727 000 000 cu yd in 1935 and 1 915 000 000 cu yd in 1934; and, the quantity carried by the much greater flood of 1933 is not known.

It would appear that the project for the control of the Yellow River for the next century should include provision for the deposit of a huge volume of the coarsest sediment, in an area above Tungchuang, diked off and reserved for that primary purpose. Below Tungchuang the project might provide for carrying the partly desilted waters, as at present, with only moderate deposits on such foreshores as may be left open between the dikes and the edges of the channel.

In selecting the proper area to carry the flood waters as distinguished from the sediment, the authors are on firm ground when they propose to give the regulated river a width that will carry the floods without making allowance for beneficial scour. The writer is not convinced that, if detention basins of the type suggested be built, it can be safely assumed that beneficial scour will result and that the width of the regulated channel can be reduced correspondingly.

HERBERT CHATLEY,[19] ESQ. (by letter).—This paper has the merit of being the first fairly complete technical description of the river in question, and the authors are to be congratulated on having been able to present so full an account.

The references to the Emperor Yü are a little unfortunate. Modern archeological research tends to show that this person is very largely mythical and an imaginative creation of the early Chou dynasts who wished to show that in overthrowing the Shangs they were recreating the ideals of their remote ancestors. There is no reliable history of China prior to about 1500 B.C.

In the references to modern studies some mention should be made of the work of the engineers of the League of Nations, Messrs. A. T. Coode and W. Nijhoff. It is true that a note as to their recommendations occurs in the paper, but their report[10] as a whole is also a valuable contribution to the rather scanty literature on the subject.

On the matter of dike positions and the Dresden experiments, the writer has published [20] a note in 1938 as to the theory of flow between set-back dikes, showing that, if the slope is constant and the flow formulas in current practice are accepted, the bank-edge position does give a larger flow for certain limited rises than a set-back position for the dikes unless the set-back is very large indeed. This conclusion is strongly and very naturally questioned; but, if it is not true, the flow formulas are somewhat incorrect and the hydraulic radius is no longer the sole criterion of flow in a bed of uniform material. The changes in the velocity-depth relation are possibly such that unless river sections are homologous, or nearly so, the mean velocity is not only an exponential function of the hydraulic radius but depends also on the shape of the section. It is worth remembering that, for constant area and constant wetted perimeter, there are two forms—one very narrow and deep and the other very broad and shallow—and it would be of great interest to know if model experiments really showed that the flow in each (with the same slope and bed material) were the same.

---

[19] Former Engr. in Chf., Whangpoo Conservancy Board, and Consultant to the Chinese Government; Cons. Engr., London, England.

[20] *Engineering*, December 9, 1938.

In this connection the writer strongly supports the desire of the authors to have exhaustive model investigations, including a careful study of the distortion effect due to vertical scales differing from horizontal ones. The writer is convinced that one great objection to the bank-edge dike position is the "plugging" of the section after a spate. In a flashy river a large deposit of silt must occur when the river suddenly falls, and this will leave a diminished section when the next rush comes. The old bed of the Yellow River south of Shantung is very interesting; in many places it is quite high above the plain. The writer is satisfied that this is largely explicable by the conditions which existed after the break of 1853. Some water was in it when the break occurred farther up; and, in addition, some water continued to enter it after the break, and the silt content of both forthwith settled and plugged the channel. It is improbable that the bed, say, at the crossing of the Grand Canal by the old channel, was as high when the river flowed in it as it is now. The writer urged this argument to Mr. Freeman when the latter advanced his straight deep channel proposals, the writer stating that after a spate the channel would tend to choke and that a new spate would back up and overflow the dikes before the plug was washed away. In this connection it should be noted from the data in Tables 7, 8, and 9 that the silt flow in a few days may represent a large fraction of the entire annual silt flow.

The gradients given in Table 1 show that the Yellow River is much steeper than the Mississippi River, even as the latter is steeper than the Yangtze. The most comparable rivers appear to be those of Northern India, several of which act in much the same way as the Yellow River. Owing to the far greater rainfall, however, and the shorter distance from the mountains, the bed material there is generally coarser. The hypotheses advanced by Mr. Gerald Lacey[21] as to regime conditions are well worth studying in this connection, although they are modified in cohesive materials.

The statement that the discharge of the Yangtzekiang above Ichang approaches 2 500 000 cu ft per sec is a little questionable (sentence preceding "Hydrological Considerations: Frequency and Magnitude of Floods"). This value almost represents the maximum flow in the lower part of that river, and as many large tributaries enter below Ichang such discharge can rarely if ever occur in the gorges.

It is noticeable that the packing of the consolidated loess is quite close, the Terzaghi pore-factor being less than unity. In the suggested measures for regulation no mention is made of the plan suggested by Capt. W. F. Tyler[22] for silt deposition basins. In view of the fact that there are areas not far from the river which are below its summer level it would be feasible to draw off considerable volumes of silt and water and thereby build up, between dikes, a dike of enormous width. The technical and administrative difficulties would be quite serious but not quite insuperable.

[22] "The Conservancy of the Yellow River"—Chinese Maritime Customs Special Reports (about 1905).

As to the delta, the writer finds some difficulty in crediting the statement that the earlier surveys have much value for comparative purposes, and the backwater function seems to be over-rated; but this is a matter for investigation.

The breach of 1938 presumably occurred after the authors had submitted their paper. The flow has apparently been transferred almost entirely into the Huai River and unless the dikes are repaired there is a serious prospect that the Hungtze Lake may become silted up and that the valuable rice lands on the east side of the Middle Grand Canal may be injured during 1939. In this connection the plan of threatened areas, given in Fig. 35, should be extended down to the Yangtze River, near the junction with the Grand Canal.

The writer sincerely hopes that American and other engineers will devote some thought and investigation with models and otherwise to the problems of this great river, which is the example par excellence of a silt-bearing stream. Messrs. Todd and Eliassen have provided sufficient data for excellent work to be done in this direction.

H. VAN DER VEEN,[23] ESQ. (by letter).—The authors' contribution to the study of the problem in question is undoubtedly the most valuable and most extensive treatise on this subject which thus far has been published and contains a mass of data never collected before. When the writer severed his connections with the Chinese Government in 1929, practically no hydrometric research work had been done as it was impossible to induce the Chinese officials to undertake to sponsor it. Lack of funds in those days, and an insufficient understanding of the importance of such investigations, were no doubt responsible for this attitude. It was extremely gratifying, therefore, when, in 1919, Mr. Freeman began his independent hydrometric study of the Yellow River in connection with the crossing of that river by the Grand Canal.[3]

It may truly be said, therefore, that Mr. Freeman was the one who gave the impetus to a further study of the Huang Ho, which Mr. Eliassen in his capacity of Engineer with the Yellow River Commission in Kaifeng, so ably continued and enlarged upon. At the same time it is to be regretted that the authors (as it seems to appear) paid so little attention to the work of J. G. W. Fijnje van Salverda[24] which was based on the reports of Captain P. G. van Schermbeek and Mr. A. Visser. This memorandum was submitted in 1887 to the Chinese Government; and, apart from describing completely the conditions of the Yellow River at that time, and explaining its peculiar characteristics, it offers valuable suggestions about possible methods for ameliorating existing conditions. More particularly, attention is drawn to the fact that much might be attained by constructing adequate protective devices at the foot of each loess cliff so as to prevent the enormous influx of silt, with which the river must cope. Mr. Freeman prized this memorandum so highly that he photographed it. He told the writer that it inspired him to learn more about that interesting subject. Mr. Freeman's passionate interest was roused by this work. Eminent engineer that he was, he saw his opportunity and grasped it to collect the valuable data which he published later;[3] but apart from influencing Mr. Freeman to shed some more light on the pecularities of the Yellow River, the memorandum contains some valuable advice which, if followed, would have improved conditions to such an extent that much of the harm done since would have been prevented. In fact, the same may be said of every sensible suggestion pertaining to improvements of the Yellow River conservancy which have been made since that time; but, as it is, much has been written about the subject and many theories have been advanced, but no work of any practical constructive value has been done.

[23] Former Advisor in River Conservancy to Chinese Government; Govt. Engr., Bureau Rijks Water Staat, Nijmegen, Netherlands.

[24] "Memorandum Relative to the Improvement of the Huang Ho or Yellow River in North China," by J. G. W. Fijnje van Salverda; submitted to the Chinese Government in 1887.

Problems have been permitted to "drag along" as in the past thousands of years. Formerly, this was due, perhaps, to the mental attitude of the river authorities in China which is best explained by the following anecdote: Once when a high Chinese official was asked why it was that no one had taken radical steps to end all those dike breaks instead of resorting only to temporary measures, he is said to have given this reply: "When one is keen on tigerhunting and there is only one tiger, would it then be sensible to kill that tiger outright during the first hunt?" There may have been some justice in this viewpoint in the old days, but it certainly does not apply to the present generation with its many brilliant young engineers who desire nothing better than to end the untold miseries which the Yellow River continues to inflict. With laudable zeal and energy these younger men have started by practising what they learned in foreign schools and universities about scientific river engineering, following the example set by foreign experts. They began to collect data after approved methods—valuable data, as is proved by the excellent paper under discussion. They even went so far as to have a model made of the river, at Obernach in Germany, where Prof. H. Engels in 1932 (assisted by Dr. Ing. Futu Li and in 1934 by Dr. Ing. Yi Shen), conducted the necessary investigations to determine whether it would be feasible to cope with the silt evil (1) by narrowing the river between dikes, (2) by building the dikes parallel, or not parallel, to the channel, and (3) by creating a straight or a curved channel either with or without wing dikes. These studies are all quite interesting, but it is questionable whether such scientific studies[25] may not be considered rather premature at this stage because, judging by the facts, the practical sides of the question seem to be receiving too scant attention.

It is quite in order to collect data and to conduct intensive investigations since this is necessary in order to arrive at the best solution. It is even an indispensable condition for ultimate success; but it is quite a different matter (and a serious one) when, in pursuing such a course, the immediate needs seem to be forgotten. By paying too much attention to certain sides of a question appreciation of the main issue is likely to suffer. It is somewhat like seeing a few particular trees but not the forest of which they form a part. Why not focus all available attention on one point only instead of spending years in a laboratory in order to ascertain, for example, which shape of river is best suitable to silt transportation? In this particular case, this is the immediate prevention of dike breaks.

---

[25] "Modelversuche über das Verhalten eines Schemmstofführenden Flusses, etc," by Dr. Ing. Chr. Keutner, *Die Bautechniek,* February 11, 1936.

It is true, as the authors state (see heading, "Scope of Investigations: Hydraulic Laboratory Experiments"), "The results gave some startling indications." Wherein lies this startling quality? The authors (and the writer, for that matter) have made a serious study of the Yellow River problem, over a long period of years, and are consequently in a position to arrive at conclusions after mature consideration. Surely, to such students there can be nothing strange about the result of investigations. In the first place the investigations proceeded from premises that are not comparable with those of the Yellow River, and secondly (as the authors remark, see heading "Scope of Investigations: Hydraulic Laboratory Experiments") the conditions bore little relation to this river. Furthermore, it is only logical to assume that, in a heavily silt-laden river, less scour can be effected in the main channel when all the silt must be transported than when a great part of this silt is allowed to settle on wide foreshores. There can be no question as to the fact that the more the river is allowed to spread over a large area like that offered by the foreshores the weaker the current will become and the more silt will be deposited. The latter circumstances, undoubtedly, will tend to place the main channel in a better position to maintain its full capacity, always provided that the banks are stabilized so that it cannot widen itself at the cost of depth, and, consequently, energy. At the same time it should not be forgotten that the process of silting the foreshore is accelerated. The banks will become higher and higher until ultimately they will only become inundated during extraordinarily high stages. Then there will be only one channel in any case. Would it not be better, therefore, to try to find a solution whereby this inundation can be postponed, at least, and, in the meantime, try to evolve methods that would minimize the influx of silt? Researches in this direction are useful indeed, and it is gratifying to note that the authors did considerable in that respect.

Under "Introduction" the authors state: "One of the real obstacles to progress, of course, lies in the lack of hydraulic knowledge of the river itself." Is this entirely true? Would it not have been possible to construct certain works which, at least, would have prevented the annual breaks, notwithstanding that deplorable lack of data, a shortcoming that could always have been remedied during the execution of protective measures? By beginning to pay too much attention to "many of the perplexities that have shrouded the river in mystery" the vision on the problem as a whole may become more or less blurred.

What is the problem in a broad sense? In a report[26] on the Yellow River problem submitted in 1921 to the Ministry of the Interior, the writer dealt with this subject in detail and also gave advice as to what should be done to mitigate the danger of, if not to prevent, the disastrous dike failures of the Yellow River.

In principle, the Yellow River is a watercourse, pure and simple, draining its catchment-basin and, like other rivers, transporting detritus. Every river fulfills this duty in its own particular way. Thus, depending on the quantity of loose soil which happens to be available on the drainage area, the steepness of its slopes and that of the tributaries, different rivers will bring more or less detritus down to the low lands and eventually, if conditions are favorable, as far as the sea. If the slope is too gentle in the low countries to maintain the energy required to keep the silt load in suspension, this load is dropped. Depending on the quantity being carried, it is either merely deposited along the banks of the river when, during floods, the water overflows (with the result that natural levees are formed with gentle slopes away from the river), or it also settles to a greater or lesser extent in the river channel itself. In the latter case, during an unusually severe freshet, the river will probably break through one of its levees after a certain lapse of time and from then on will follow a new course in which the same cycle is repeated. This is called plainbuilding, a process which continues on and on until eventually a certain equilibrium is reached, whereby the slope of the plain has become sufficiently steep to enable the river to develop a gradient that is capable of imparting to the current the energy that is required to carry all the silt as far as the sea. In the case of most rivers plainbuilding is completed, or practically so, because erosion in the hills has discontinued (or at least has diminished in intensity), or because the topographic features of the country lend themselves to a speedy solution of the problem. Unfortunately, the Yellow River basin has neither exhausted its supply of silt not does its geographical location render a rapid solution possible. Between the hills and the sea there is an enormous plain which the river must traverse. At the same time the supply of silt seems to be unlimited. Consequently it is reasonable to conclude that because the river is passing through the middle phase of its stabilization (a gigantic process) it would be foolish not to abide by it; or, what is still more foolish, to try to fight against it. Only if river engineers are prepared to accept this fact as indisputable, will it be possible to succeed in ameliorating the conditions affecting the Yellow River problem. In this connection it will be well to recognize the fact that such steps will only tend to mitigate an unpleasant state of affairs; they will never be able to solve it except in a degree.

---

[26] *De Ingenieur*, Royal Dutch Inst. of Engrs., 1934, No. 33 (abstract).

A few thousand years ago, when the Chinese began to build dikes along the Yellow River they interfered with Nature's process of plainbuilding, inasmuch as they restricted the process to a narrow strip of land. The effect, of course, was to hasten the forming of a steeper gradient which, in turn, created a stronger current so that more silt could be transported to the sea. Furthermore, the river was made to run on a ridge, with the result that if Nature now asserts its right to continue plainbuilding the gravest consequences ensue for those standing in her way.

To make a sweeping statement, it would have been infinitely better for the present generation if past generations had permitted the Yellow River to do its work unhindered, or if those in the past who were entrusted with its care had been far-sighted enough at least to permit the river to follow another course. This was not done, however, and therefore the present generation is faced with the fact that the river runs on a ridge where it is kept in bounds between dikes which are more or less far apart. Within this cramped space Nature goes on with its process of plainbuilding in an endeavor to establish a slope sufficiently steep to create an equilibrium between the volume of silt that must be carried, and the carrying capacity of the current. It is evident, therefore, that, as long as such a slope has not been established, this narrow strip of a plain (which, by Nature's right, belonged entirely to the River) will continue to rise higher until the final stage is reached. The question is, "When will that event occur?" Perhaps this moment might have been accelerated if: (1) The space allotted to this restricted plainbuilding had been restricted still further—in other words, if the dikes had not been so far apart; and (2) if the main channel had been given a fixed alignment. However, for the moment, it is probably best to leave this question alone.

The river channel is left free to shift from one side to the other between the dikes. Time after time, therefore, the dikes are exposed to a direct attack of the current, at one place or another. Inevitably, they collapse and permit the disastrous inundations in the low-lying, adjacent, great plain. The higher the ridge on which the river runs becomes, the more devastating will be the consequences of a dike failure. Why then, one may well ask, are not better precautions taken to protect those dikes? In the course of many centuries the Chinese have developed clever devices for dike protection; but these are only applied whenever a dike is actually threatened; never before. This seems illogical, but it is often difficult, if not impossible, to predict the particular spot at which the dike will be attacked during a freshet season. It would be necessary in order to afford entire safety from flood to protect every foot of dike. It is clear that such a procedure would be enormously costly; and the Chinese are not a race that throws money away at random. Why, then, protect a dike when one is not sure that it will be necessary? This system is mainly responsible for the bad reputation of the Yellow River, whatever its other bad points may be.

The crux of the question is in dike protection; and it is quite immaterial for the moment, whether dikes should be far apart or not, which dimensions should be given to the channel so as to enable it to carry a maximum quantity of silt, whether highly silt-laden water follows the same hydraulic laws as clear water, etc. All these are extremely interesting problems in themselves and, therefore, should receive due attention in time; but at this stage they are of no consequence.

Since it is beyond question that the main cause of dike failures is the direct attack of the river (that is, the deep-water channel) on the dike, it is obvious that the only method of preventing those attacks is to prevent the main channel from running too close to the dikes.

In the writer's report[26] to the Chinese Government he explained in detail how this could be done. The method he advocated was to construct an adequate system of groins and parallel works with a view to keeping the channel in a fixed position. As a matter of fact the authors advise, in principle, a similar procedure. The width that should be given to the channel is a matter of conjecture, at least for the present. It would be advisable, however, to make it ample at the outset because it is far less costly to lengthen the groins, in case they should prove to be too short, than to make them shorter. Over a certain length these regulation works should not be higher than the foreshore, although they should slope upward slightly from the new channel alignment (normal lines) in the direction of the dikes. Perhaps this will render it necessary, at some places, to give them a slight elevation with respect to the general ground level. The remaining length of the groins—that is, the distance outside of the future high-water channel—can be raised above high-water level.

Groins should be built close together in those stretches where the new river alignment is designed close to the present side of the channel. Of course, it is not necessary to extend each groin as far as the main dike; but a series of groins may be grouped together by means of a dam parallel with the river, connecting the latter with only one dam across the foreshore with the dike. It is the writer's firm belief that in this way the danger of breaks can be reduced to a minimum. At the same time the channel, being kept within bounds, cannot widen itself during freshets as it does now; consequently no dissipation of energy can occur (at least from that cause) so that, incidentally, more energy will be available for carrying silt. Whatever the relation may be between the velocity of the current and its capacity for keeping silt in suspension, there can be no doubt that a river which is free to erode its channel (or if capable of maintaining one course, widens it at the expense of serious scour) cannot possibly have the same capacity for carrying a load as a channel whose width is fixed.

After these structures have been built, or rather during their construction, the hydrology of the river should be studied rigorously. The writer is a fervent adherent of hydraulic studies and has a firm belief in the usefulness of laboratory experiments; but, at the same time, he is of the opinion that great care should be taken to insure that the practical aspects of the problem are not pushed into the background. Consideration of practical aspects should always predominate.

Under the heading "Flood Control and Regulation: Channel Stabilization Methods," the authors describe a procedure that coincides practically with that of the writer.[26] The latter differs only in comparatively minor points such as the elevation of the groins, and their direction. In Holland where groins have been used extensively there are adherents to each mode of location, different directions being advocated, with different supporting arguments in each case. There is something attractive in deflecting groins, however, as they tend, somehow, to concentrate the current; but, after all, their radius of action is small compared with the width of the river, so that it is doubtful whether they are worth worrying about. That laboratory experiments in this connection "are likely to repay themselves a hundred-fold," therefore, seems to be a rather strong statement.

There is one other item on which the writer would like to comment; namely, the question of spacing the groins. More than a century of experience in Holland has taught engineers that the spacing should preferably be not more than one and a half times their length, and even less if that length should be disproportionate to the width of the channel. Hydraulic laboratory experiments conducted in 1938 supported this view. The spacing has little to do with "a more or less erosion-resisting quality of the soil," however. It is governed principally by the fact that it determines "boundary conditions": The better the spacing, the better these conditions will be, inasmuch as friction is reduced to a minimum and no energy is wasted at the cost of loss of head and other losses. If that result has been attained, the river banks are adequately protected, whatever the quality of the soil may be. It is a well-known fact that flow can be made smoother by careful planning of training works and, although turbulence plays an important rôle in keeping the heavier particles moving, in this particular case, where the silt is extremely fine, more can be gained by saving energy than by wasting it in order to create turbulence. However, laboratory tests should certainly be made in an effort to shed more light on this question.

Under the heading "Flood Control and Regulation: Influence of the Delta," the authors have verified the writer's views on the same question on the basis of the interesting data which they have collected. In fairness to Mr. van Salverda,[24] however, it should be noted that as early as 1887 he called attention to this particular item. In this connection, it may be of interest to recall the fact that, acting on the advice given in Mr. van Salverda's report, the Chinese Government purchased a bucket dredger in order to clear away the silt in the channels through the delta, just as the authors now propose exactly fifty years later. This dredge arrived in the early nineties; but it foundered soon after it was placed in service and now lies deeply buried in the silt which it was supposed to remove. It would not be surprising if the Chinese in those days ascribed this mishap to a revenge of the river gods who were angered that mortals dared to interfere with their work. The writer does not belong to the class of higher beings who, according to the belief of the masses in China, rule the waters; neither is he angered about what was done; and yet he too does not approve of the method advocated by the authors for the simple reason that it seems to him like "fighting windmills." It seems strange that the authors, who so admirably indicate the means of mitigating the silt evil under the general headings "Hydrological Considerations," and "Flood Control and Regulations," should include dredging through the delta as a remedy. The effect of dredging would be insignificant compared with the excellent measures which they propose in the aforementioned chapters, with which the writer is entirely in accord.

The writer does not believe in detention basins in the hills, however. These must be considered as temporary measures only, without any lasting merit. The writer is keenly in favor of spillway basins in the plain, however, not so much because they will reduce the discharges and flatten the peaks of the freshets, but because they will tend to desilt the water. In doing this the natural plainbuilding process with which Man has interfered is at least restored to some extent. For the same reason the writer considers the by-pass channels mentioned by the authors to be an excellent means of ameliorating conditions.

Before ending his comments on the authors' valuable paper the writer wishes to state that he is fully convinced that if the Chinese Government could be induced to accept the theories so ably expounded by the authors, and could be made to put into practice the remedies that have been advocated, with the least possible delay, the untold miseries, which heretofore have made the Yellow River the scourge of China, would cease to exist.

It seems regrettable that the authors have left China and thus, perhaps, lack the opportunity to continue their work in connection with the fascinating Yellow River problem.

C. S. JARVIS,[27] M. AM. SOC. C. E. (by letter).—Many essential data hitherto unavailable to the engineering profession have been presented by the authors, and they have suggested such remedial measures as seem to have most practical value, according to their intimate knowledge of local conditions prevailing throughout the Yellow River Basin.

---

[27] Hydr. Engr., SCS, Dept. of Agriculture, Washington, D. C.

From the basic information and also from the recommendations thus presented, it appears that the most dependable and positive relief from floods would entail a combination of head-water storage and detention works, extensive land surface treatment for the express purpose of soil and water conservation, and such bank protection, flood spillways, and by-pass facilities as would best afford the needed channel capacity and stability, together with the desired security for inhabitants and their properties. Moreover, there is assurance that the most critical sections of protective works may be located and strengthened well in advance of the flood stages, instead of waiting until the danger is imminent or actually upon them, according to the ancient fatalistic practice.

It is interesting to note that the total Yellow River drainage area is nearly twice that of the Ohio, yet its maximum estimated discharge (900 000 cu ft per sec) was only about one-half of that recorded in the Ohio River (1 600 000 cu ft per sec at Paducah, Ky., in April, 1913, and 1 850 000 cu ft per sec at Metropolis, Ill., in February, 1937). Furthermore, the Yangtzekiang drainage area and maximum discharges both compare fairly closely with those of the Mississippi River.

The authors state (in the text preceding "Hydrological Considerations") that the Wei Ho (drainage area, 56 000 sq miles) is almost as important a flood and silt carrier as the Yellow River itself. Although it is less important as a low-water feeder, it appears that the critical areas awaiting corrective and regulatory measures must be within this tributary basin; and these main flood-source areas may constitute only a minor portion. Detention and storage facilities would be capable not only of reducing damaging flood crests, but also of augmenting the low-water flow as a natural consequence.

The use of auxiliary flood channels and lateral waterways running nearly parallel to the river course, and supplied by controlled sluices through the embankments, with gateway sills set low enough to divert a portion of the bed-load as well as some of the suspended material along with the released flood water, might go far toward maintaining channel capacities through the removal of bars, or by preventing their formation. At the same time, such sluicing might contribute toward filling in the depressions and undrained areas adjacent to both the irrigable tracts and also the alluvial ridge along which the river now wends its way, continually chafing under the restraints imposed by barrier embankments, and searching for some means of escape to the neighboring low-lands.

E. W. LANE,[28] M. AM. SOC. C. E. (by letter).—Probably no engineering project under serious consideration would do more to relieve human suffering than the control of the Yellow River in China. In their work on this problem, in the field, the authors have already made major contributions, and this paper, by preserving through times of disorder the most important facts and engineering data previously collected, may well be another major contribution to the success of this project. Small amounts of information on the Yellow River are widely scattered through engineering literature, but in no other place can one find a wealth of material at all comparable with that presented by the authors.

---

[28] Prof., Hydr. Eng., Hydr. Laboratory, Univ. of Iowa, Iowa City, Iowa.

The Yellow River is not only a stream of water, but it is also a stream of sediment, and any engineering plan which will be more than a temporary measure must take this into account. The Yellow River is not unique in this respect—the same thing is true of most rivers. The writer believes that a great deal of trouble will occur in the future because sufficient provision has not been made in a number of engineering projects for the flow of sediment as well as the flow of water. However, the Yellow River is unusual in that the quantity of sediment carried is so great that the necessity of a consideration of it is more readily apparent. In some other streams the action will be the same but it will go on at so slow a rate that the results will be apparent only after many years.

A comprehensive solution for the flood problem of the Yellow River, therefore, must be complete both from the standpoint of the water stream and also from that of the sediment stream. From the practical standpoint, the best plan may be to undertake first only the control of the water stream, since such a procedure may give the greatest return on the money which can be raised in the early years for carrying out the project; but in order to select the best plan it is necessary to view the whole problem and weigh all the disadvantages of temporarily neglecting the control of the sediment. Some of these disadvantages may not be readily apparent without a careful study of the control of the sediment stream, but may prove to be so great that an apparently satisfactory solution from the limited viewpoint may turn out to be much less desirable than one which, without considering the sediment aspects, appears relatively unpromising.

In order to appraise correctly the problems due to the sediment stream, it is necessary that the laws governing the transportation of sediment be known. Unfortunately knowledge of these laws is very imperfect. However, rapid progress is being made in this field, and it is confidently believed that before long it will be possible to handle problems of sediment quantitatively as engineers now handle those of water. At least approximate solutions of bed-load problems have been available for some time, and quantitative solutions of suspended load relations are being developed. One of the greatest needs for a solution of the Yellow River problem is a further working out of these laws. It is probable that the difficulties of controlling the sediment will be as great or even greater than those of controlling the water, and the need for a knowledge of the laws governing sediment will be as essential to a proper solution as a knowledge of the laws controlling the flow of water.

If the Yellow River were only a river of water, the data presented in this paper indicate that its flood problem probably could be solved with comparative ease by retarding basins. Because of the extremely short duration of the flood peak, the conditions are unusually favorable to retarding basin control. The presence of the heavy sediment load, however, seriously complicates the situation, and in any flood-control plan it must be given most serious consideration.

As shown by the profile given by Colonel Dent, there is a distinct flattening of the gradient of the river where it leaves the gorge section at Mengtsin and starts across the plain. This point is just below the region in which the most promising storage site appears to be located. The slope in the bottom of the reservoirs would be over six times that just below Mengtsin. As the writer has explained previously,[29] the water flowing across the sediment deposited in the bed of the flood-control basin would pick up a much greater load of sediment than it could carry across the plain, and therefore extensive deposit would take place down stream from the reservoirs, where the slope is flatter. This deposit would fill up the bed of the stream and might raise the elevation sufficiently to cause the overtopping of the levees. The possibility of such action should justify a thorough study of this point before a final decision on retarding basins is made. The existing bed is the product of the filling and scouring of the river with its present sediment load, and any conditions, such as the construction of the retarding basin, which would add materially at frequent intervals to the sediment load, would probably cause an increase in the average level of the river-bed. The raising and lowering of the bed levels mentioned in the paper are believed to be a demonstration of the sensitiveness of the river to changes in the character or amount of the sediment load.

The authors have presented a very complete discussion of the Yellow River problem from the standpoint of the water stream, but further consideration might be given to the problem from the standpoint of the sediment stream. Viewing the situation broadly, it seems that the sediment load of the Yellow River must be handled in one or more of the following three ways: (1) It may be reduced by keeping the soil in place on the land by erosion-control methods; (2) it can be carried out to sea and deposited on the sea bottom; and (3) it may be stored on the land surface by taking it out of the river. Probably the best solution will be a combination of the three methods.

In a paper entitled "Soil Erosion and River Regulation with Special Reference to the Yellow River,"[30] Mr. Eliassen has discussed at some length the possibilities of reducing the sediment load of the Yellow River by soil-conservation methods. Based on the cheap labor conditions existing in China and the knowledge gained in soil-control engineering in the United States, it seems probable that at least part of the sediment load should be taken care of in this manner. The benefits would be not only that of flood control but also of increased food supply which could probably be produced by the vegetal cover developed in the erosion-control process. While erosion control has no doubt been practiced in the past as a means of conserving agricultural land, its value as a flood-control measure has not been considered, and if financial support were given to the work because of the flood-control benefit it is possible that an extensive program along this line might be feasible. If practically all the sediment could be retained on the land, the clear water in the river would pick up a large volume of sediment from its bed and carry it to the sea, thus enlarging the river channel, and eventually solving the flood problem. It is improbable that anything approaching complete erosion control will be practicable, but something between complete control and the present conditions will probably be a part of the best plan for flood control.

---

[29] *Journal*, Assoc. of Chinese and American Engrs., Vol. XVIII, March–April, 1937, p. 130.

[30] *Journal*, Assoc. of Chinese and American Engrs., January–February, 1936.

The second method, by carrying the sediment to the sea, will no doubt be a part of any flood-control plan. As long as the Yellow River flows over a bed of fine material it will not be feasible to prevent it from carrying a large load out to sea. Although this disposition does bring in some serious problems, as the authors have pointed out, these difficulties are probably less than those of the third method, and, therefore, deposition in the sea should be encouraged as far as possible. Since the fall of the river in crossing the plain cannot be materially increased without raising the level at the western side of the plain much higher that it is now, it is probable that, aside from maintaining the levees intact and possibly regulating the channel across the plain to keep it deep and straight, little can be done to increase the ability of the river to transport sediment.

If this is the case, the amount that can be carried out to sea under the most favorable conditions will be considerably less than that now brought into the plains section by the river, and unless a major reduction in volume can be made by soil-conservation methods, any long-time plan for Yellow River flood control must include provision for controlled sediment storage. In other words, for complete control of the floods, if more sediment enters the plains section of the river than can be carried out to sea, the excess must be stored by some controlled method. The excess which now exists may be reduced by soil conservation and possibly by producing some increase in the carrying capacity of the river, but unless the excess is entirely eliminated by these methods, disasters cannot be permanently prevented except by means of sediment storage under controlled conditions.

There can be little doubt that in the past the flow of sediment in the river at the western side of the plain has materially exceeded that which passed out of the mouth at the east side, and therefore that there were large quantities of material deposited between these two points. When the river changed its course in 1851, the meager accounts available indicate that the new course to the sea was along the line of a stream which had a much flatter gradient than the Yellow River and therefore flowed at a lower level. The flow through the breach in the dikes entered this low-level stream, and the bed of the Yellow River above the break was cut back, lowering the bed materially. Since this change of the river's course took place, the bed of the new portion of the channel filled considerably, and, as stated by the authors, an adjustment is still taking place in the vicinity of the break. In this process tremendous quantities of sediment have been deposited, which accounts for part of the excess of sediment inflow over outflow in the plains section, as previously mentioned.

Another part of this excess has been deposited on the land by the flow through the breaks in the dikes. When such breaks occur, the heavily silt-laden water flows over the land and deposits tremendous quantities of sediment. In some cases the flow returns again to the Yellow River in a comparatively clear condition and goes on out to sea. In other cases it goes overland to some other stream leading to the sea, but in either event a large part of its sediment is deposited on the plain.

Unless the inflow of sediment at the western side of the plain can be made to equal that flowing into the sea at the eastern side, a levee system alone will not be a permanent solution for the Yellow River floods, since the sediment storage which takes place will raise the bed of the stream and cause progressively higher flood levels until so great a height is reached that levee construction becomes very expensive and insecure. In this condition, if a break occurs, the elevation of the river-bed will be so much higher than the land that the water cannot be forced back into the channel. The raising of the bed will increase slightly the amount of sediment which can be carried out to sea, but since a 5% increase in slope would raise the river level about 15 ft at the western side of the plain, no great increase in average slope can be attained without raising the river at that point to unsafe levels.

Since it seems unlikely that in the plains section of the river the combination of reduction in sediment inflow by soil conservation and the increase in sediment outflow can reduce the excess of inflow over outflow to zero, some form of controlled sediment storage must form a part of any permanent plan for the control of the Yellow River floods. If this is the case, such storage will have to be carried on continuously and sooner or later the basins for the deposit of the sediment will be filled. It appears, therefore, that no set of works can in themselves be a complete solution of the flood-control problem, but sooner or later other works will have to be constructed and the control of the Yellow River will therefore be a continuing process of construction work.

Another reason why continuous work will be necessary is that as the sediment continues to be carried out to sea, the mouth of the river will move outward, as explained by the authors. The river levees, therefore, will have to be extended seaward and those now near the sea will have to be raised. Although this process will no doubt be slow, it seems to be inevitable. In considering the best plan for controlling Yellow River floods, therefore, it should be realized that no solution will entirely eliminate the necessity of future construction, and therefore works which are obviously not a permanent solution should be considered along with those which may appear to be, but in reality are not, permanent solutions. When one considers the necessity of controlled sediment storage in any plan for permanent flood control, with the consequent expense and difficulties due to opposition of land owners, the advantages of soil conservation from the flood-control standpoint become apparent. Of course, such measures also would be a continual expense but it seems certain that a large program of work to keep much of the soil in its place will be cheaper and more satisfactory than artificially storing the soil after it has reached the river.

The foregoing statements must not be construed as showing that better levees should not be built along the Yellow River or that those now in existence should not be maintained. The damage caused by a levee break is so great that better levees might pay for themselves long before they became inadequate. It may not be possible for some years in the future to finance the works necessary for complete control. What the writer wishes to emphasize is that eventually sediment storage will probably be necessary, and that the best possible plan of action is more likely to be found both for the immediate future and for more distant times if all the factors are considered. Therefore, every effort should be made to collect the information necessary for a complete picture of the problem. In the writer's opinion this would include the collection of more data on the composition and concentration of the sediment carried by the river and its tributaries and a better working out of the laws governing sediment transportation.

Sediment storage for the improvement of streams is no new thing in China. On the Yung Ting Ho above Tientsin there is a large area in which silt has been depositing for many years and which has permitted the Hai Ho from Tientsin to the sea to maintain a navigable channel. The writer has not been able to find any statements as to when this sediment-storage basin was constructed and whether or not it was built with that function in view, but in any event it has served very well for this purpose until recent years when it has become so full that it is no longer effective and the channel of the Hai River has been badly deteriorated. To replace this sediment-storage basin a new one has been constructed and, it is understood, is now functioning satisfactorily.

Three principal plans for controlled storage of sediment might be developed: (*a*) Storage in reservoirs west of the plain, (*b*) storage in basins along the river in the plain, and (*c*) storage at the west side of the plain. The authors have mentioned good sites for reservoirs in the section between the Peiping-Hankow Railway and the mouth of Wei Ho, and also in the vicinity of the Hu Kou Falls. Sediment storage could probably be obtained at reasonable cost at these sites. As stated before, the reservoirs would undoubtedly fill rapidly and eventually new storage space would be required. In the early stages of filling they would serve admirably for retarding basins and would have a dual purpose—the reservoirs could be used for the generation of water power and in the early stages of filling would have available considerable storage and pondage space. As they became filled, however, the power generating plants would have to be operated on a run-of-river basis. Thus the reservoirs might be used either for combined retarding basin and silt storage, with the retarding ability eventually being lost, or as combined water power and sediment storage, with part of the water power benefits eventually being lost. Since the vicinity of these basins is well supplied with coal, it would seem that the combination of sediment storage with retarding basin action would probably be the best. The use of these basins as detention basins would also permit their use for flushing out the river down stream by storing clear water during low-flow times and releasing it with higher flows during short periods.

The necessary sediment storage could be accomplished by deposit in predetermined areas in the plain section during floods, when the water level was high enough to permit overflow of the land along the stream. By building a pair of dikes parallel to and outside of the present ones (where secondary dikes are not already in existence), with cross-dikes connecting the outside and inside dikes at intervals, a series of basins could be formed in which the water could be let in at the upper end through sluice-ways and the desilted water let out at the lower end. Such a scheme would build up the land along the river banks and thus add to the security from disastrous levee breaks. The desilted water released at the lower end of these basins, upon flowing back to the river, would pick up a load of sediment from the river banks and bed, and thus enlarge the capacity of the river channel. The amount of material picked up, however, would probably be materially less than that deposited, since the former material would average much coarser than the latter. The construction of the second dike system would be a considerable expense, although it would not have to be as heavy as the primary system, since in case of a break only the water in the desilting basin would be released. The principal disadvantage of this form of sediment storage is the damage resulting from taking so large an area of land out of cultivation or the periodical destruction of the crops which would occur if this land was cultivated, since the Yellow River floods come during the growing season. This plan could be put into operation only under a strong central government and would no doubt meet with a great deal of opposition from the present owners of the land included in these storage basins.

A third plan for storage of the surplus sediment would be to construct basins where the river emerges from the hills, causing the river to form a sort of debris cone by spreading it out over the plain in this vicinity under controlled conditions. This plan would have the same disadvantages as that previously described but might be cheaper. This form of sediment storage might be combined with retarding basins, the sediment carried out from the retarding basins after the floods being desposited under controlled conditions on the plain. All three plans have the disadvantage that they would require continuous work, but no form of flood protection for the Yellow River seems feasible which can be constructed immediately in its final form.

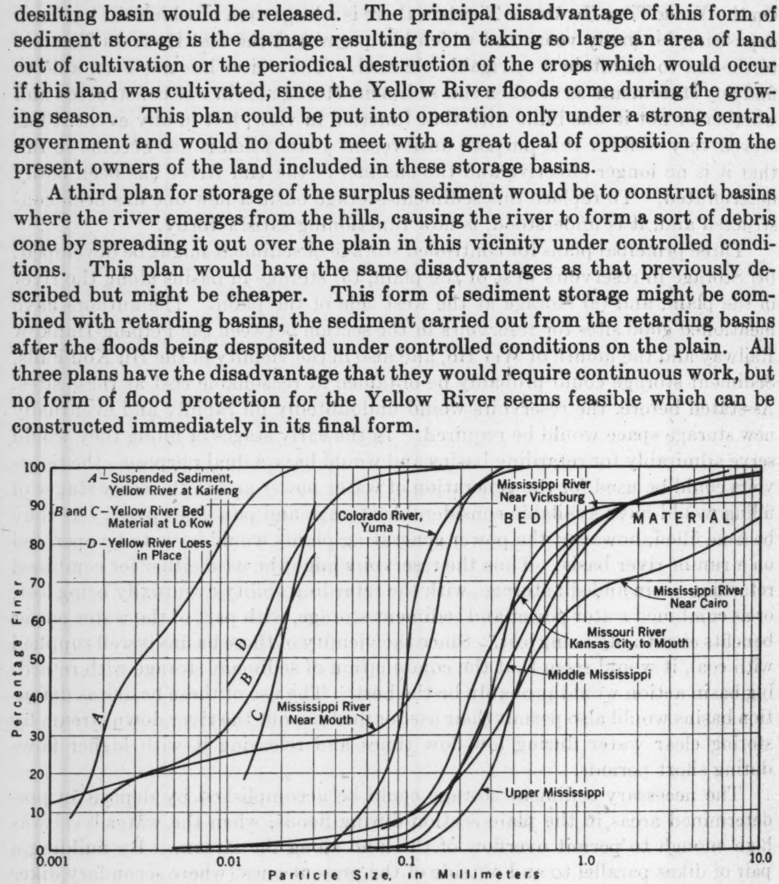

FIG. 37.—COMPARISON OF SEDIMENTS, YELLOW AND AMERICAN RIVERS

The authors have presented a large amount of data on the silt load of the Yellow River, but no data have been given on the size of the particles of which this silt was composed. The writer understands that analyses of numerous silt samples have been made by one of the authors, but that the data are inaccessible because of the war. It would be a great misfortune if this information should be permanently lost, since sedimentation investigations are showing conclusively that a knowledge of the particle size or settling rate is essential in studying sedimentation problems.

Very little information on the size of sediment in the Yellow River is available, but three curves showing the compositions of Yellow River sediment are shown in Fig. 37, the data being taken from "Die Rigelung des Hwangho," by Li Fu Tu. The left-hand curve, for material at Kaifeng, is probably typical of suspended material in the river. The remaining curves give analyses of bed material of a number of the rivers in the United States. The finest of these is the bed material of the Colorado River near Yuma, Ariz.

This diagram strikingly illustrates the difference in the character of the Yellow River sediment and that found in the rivers of this country. The median diameter of these various samples is as follows:

Sample	Median diameter, in millimeters
Yellow River suspended sediment at Kaifeng	0.0033
Yellow River loess in place	0.012
Yellow River bed material at Lo Kou Chen (average)	0.018
Colorado River bed material	0.10
Missouri River bed material	0.28
Lower Mississippi River bed material at mouth	0.13
Lower Mississippi River bed material at Vicksburg, Miss.	0.33
Lower Mississippi River bed material near Cairo, Ill.	0.53
Middle Mississippi River bed material	0.38
Upper Mississippi River bed material	0.48

A comparison of bed material shows that the average of a sample from the Yellow River was about one-fifth the size of the Colorado River bed material, one-seventh that of the Mississippi at its mouth, and from one-sixteenth to one-twenty-seventh that of the various other rivers for which data were given. It seems obvious that the reason why the Yellow River can carry such heavy loads of sediment is that the material carried is so extremely fine. These samples were taken in the plain section of the river, but the gorge section above Mengtsin carries a certain amount of quite coarse material, as shown by the fact that this was sufficiently large to break the glass bottles used in the sampling device, and metal bottles had to be substituted. This coarse material apparently settles out in the vicinity of Mengtsin in a sort of debris cone and does not reach the plains section of the river.

GEORGE HIGGINS,[31] M. AM. SOC. C. E. (by letter).—Valuable material and suggestions have been furnished by the authors. The writer suggests that the entire length of that part of the river in which the flow is above the level of the adjacent country shall have its banks constructed to act as spillways. This means a spillway on the left bank about 465 miles long, and one on the right bank about 450 miles long. These are approximately the lengths of the dikes or levees already constructed. It is suggested that, in general, a shallow flow of flood waters over the adjacent country on both sides of the river would benefit the land, which sometimes suffers from drought, and would enrich it with the silt derived from the uplands. Not only that, but the relief from high flood conditions which the river would experience in consequence of the diversion of so great a proportion of the flood waters would greatly lessen the danger of concentrated flood waters which now sometimes break through the levees.

---

[31] Cons. Engr., Melbourne, Victoria, Australia.

In effect, the proposal is to follow Nature's procedure. Heavy rains wash material from the hill country into the valleys where much of the mixture of solids and liquid is carried along. Sooner or later, heavier particles will settle on the stream beds, raising them; and, when these beds are high enough and the banks low enough, overflow will occur. Generally such overflow is accompanied by deposition of silt on the land adjacent to the stream, heavier and coarser particles lodging close to the stream, the finer being carried on. This accounts for the form which cross-sections present—gradual surface slopes falling away from the relatively higher river banks. Rivers in all parts of the world exhibit this natural action.

On the other hand, if it is attempted to confine flood flows to a definite channel by erecting artificial banks, the bed will continue to rise in consequence of the subsidence of the heavier particles which the water is carrying forward—this is the ultimate result even if, at times, the action of the current may be a scouring one. One of the most notable examples of this effect is furnished by the Po River in Italy, whose banks have had to be raised several times to keep pace with the higher water level due to the raising of the river-bed. About 5 000 000 persons live on areas protected by these banks, and, when the banks break through (as they have done, unfortunately), the results are disastrous.

"China's Sorrow," the Yellow River, carries an enormously greater proportion of sediment than the Po, and the fact that much of this sediment is deposited on the river-bed as a result of floods is well known. Were it not that the artificial banks have frequently broken through, the rate at which the bed rises would be still more rapid. What will happen if the levees are made unbreakable? The channel will fill up, and, if the banks are raised higher, the channel filling will continue. Terrible as the results of bank fracture have been in the past, they will be worse if still higher banks break through. In any case, there must be a limit to this bank building.

The simpler plan seems to be to strengthen the river's natural banks so as to make them suitable to act as spillways, and to let the river deposit silt on them and outside them at its natural slope—probably not steeper than 6 in. to the mile. To a great extent, the river itself will raise its own banks as well as its bed. Man may help, here, to direct the natural action: By strengthening the natural banks; by raising them in places so as to keep the flow over the crests approximately uniform in depth; by checking any tendency for the flow over the country's surface to concentrate itself in depressions and cause scour there; by building groins or other means for deflecting the river's current away from the bank which it may tend to undermine; by encouraging the growth of vegetation on the loess and other surfaces from which the silt is derived; by interposing positive checks to the flow of silt from eroding surfaces; and, generally, by working with Nature.

Such details as the raising of dwellings and providing for the safety of live stock during the month or two that the shallow flooded conditions may last may well be left to the resourceful people who have displayed remarkable skill and endurance in the past.

In the writer's opinion, the existing levees should be removed. If they remained, they would only obstruct the even flow of silt-laden water over the surface of the country; and this flow is desired. The material in the levees would be useful, in places, for the strengthening of the river banks, thus enabling them to act as spillways, and also for forming groins or training-walls in the channel.

As for the height of the banks, which would become spillway crests, the writer suggests taking present bank levels, where they have not been altered artificially, as a guide at the outset. Absolute uniformity of depth flowing over the crests will be unattainable. Local falls of rain would prevent such uniformity, producing "flood waves," as they do. Moreover, every large flood has its "peak," and the peak passes down stream while gradually flattening itself out.

Earthquakes are known to affect the country through which the Yellow River flows. Any shattering due to this cause will be much less serious with river banks of indefinite width than with narrow banks formed by levees. Ice jams may be expected to occur in the future, as in the past, and the consequent "heaping up" of water locally will have to be accepted.

In common with all irrigation systems, there is a possibility of the irrigated land becoming alkaline, necessitating drainage, which is not a simple matter in country so nearly level as that here considered; but such difficulties, and probably many others, will have to be faced. The aim must be to eliminate difficulties as far as possible.

The growth of the delta has occasioned anxiety to many engineers who have studied the Yellow River problem. This growth would be greatly lessened if much of the silt were deposited on the country adjacent to the river. The "plains" through which the Yellow River flows for the last 500 miles of its course have evidently been deposited as deltas. Allowing Nature to continue its processes should not lead to conditions inferior to those existing before Man interfered. In any case, even if it were possible to form and maintain a channel between levees which will not overflow, it will not be possible to discharge all the silt into the ocean. A certain quantity will be deposited on the river-bed, making it necessary to raise the levees frequently. Where would that end? It would create a channel on top of a steep embankment, rising higher and higher as time goes on! There is no satisfactory end to this process.

O. J. TODD,[32] M. AM. SOC. C. E., AND S. ELIASSEN,[33] ASSOC. M. AM. SOC. C. E. (by letter).—Since this paper was written, in 1938, there has been a marked change in the lower course of the Yellow River which is no longer flowing in the diked channel north of the Shantung Mountains, but across the plains to the southeastward from a point nearly 40 miles west of Kaifeng. It has joined the Huai River and, together with that river, empties into Hungtze Lake east of the Tientsin-Pukow Railway in Kiangsu Province and from there, via several channels, into the Yellow Sea. Some of the flow follows the course of the Grand Canal to the Yangtzekiang 700 miles south of the 1937 outlet of the Yellow River on the Gulf of Chihli.

---

[32] Cons. Engr., Palo Alto, Calif.; formerly, Cons. Engr. to the Yellow River Comm. and Shantung Govt., Peiping, China.

[33] Engr., Messrs. Höyer Ellefsen, Oslo, Norway; formerly, Engr. in Chg., Survey Dept., The Yellow River Comm., Kaifeng, Honan, China.

This latest great change of course reminds observers of the consequences of a "back to Nature" program. If human beings are going to live and carry on their daily activities in this fertile region, the Yellow River must be held to a channel that is as stable as possible. The inhabitants must have a sense of security if they are to live in peace and build permanent homes. Railroads, motor roads, and canals must all be made secure against serious flood attacks. A section of the Lunghai Railway has already been buried in silt since the dike break of June, 1938. It will not be long until sections of the Tientsin-Pukow Railway in Kiangsu will be similarly threatened. A river which, annually, can fill an area of 300 sq miles with silt to a depth of 5 ft must not be permitted to go uncontrolled across a fertile plain where the average population density is greater than 600 per sq mile.

The question may be raised as to which of the two general routes should be chosen as the regulated course of the river—the one north of the Shantung Mountains to the Gulf of Chihli, or the one south of these mountains to the Yellow Sea. Both from technical and social-economic considerations the northern course is decidedly preferable. The distance to the sea is shorter and will remain shorter for the next two centuries even if nothing is done by way of soil-erosion control of the inland areas. Also, the northern route has no complications with other river systems such as would be found along any southern route that might be selected. The northern route is flanked on the south for a distance of 90 miles by the foothills of the Shantung Mountains, making one dike unnecessary in that region; and, since a dike system exists which can be utilized, in part, in a permanent plan of control, it will obviously be less costly to regulate the northern course (of 1851 to 1938) than any southern course, including that being followed since the summer of 1938. The latter would require a new diking system with costly regulating works to control the floods of the rivers draining the southern slopes of the Shantung Mountains, as well as the floods of the Huai River. Since these rivers have serious flood problems of their own, flood control would be complicated by routing the Yellow River that way. The Huai River is notoriously difficult to handle in time of high flood.

The fact that the Yellow River has been so altered in its course since the preparation of this paper does not mean that the problem of control is essentially different from that outlined by the writers. The present (1939) course of the river is likely a temporary one, although it might be maintained to advantage while the former (1851 to 1938) course is being regulated as suggested by the writers. Much of this work could be done "in the dry," at a great saving in costs, and the river then diverted back into the regulated channel from the new (since 1938) course.

Mr. Beardsley asks if it will be practical to fill, with silt, a number of shallow lakes and marshes along the old and former diked courses, and thus convert these areas into good, arable land. This is quite feasible and desirable. The areas are small, however, and confined to narrow strips of land just outside the dikes. During the decade 1929 to 1939, a number of siphons were constructed for the purpose of drawing silty water from the Yellow River in order to irrigate, fertilize, and reclaim just such areas. Experience has shown that these siphons need careful watching in order to avoid drawing in fine sand which may suddenly appear at the surface of the river, due either to small freshets or to the throwing into suspension of bed silt which contains coarser material. Lands have been ruined by careless operation of such siphons. The best success thus far has been obtained along the lower course in Shantung. Several siphons installed in 1936 near Kaifeng had not been in operation long enough to warrant any remarks as to their merits when the war broke out, preventing further experiments.

However, it is the larger aspect of broad-flooding wide areas during floods in order to control the silt that is of major interest. It involves the moving of a population estimated at 200 000 from an area of 400 sq miles, every 8 or 10 yr, into other areas prepared for them, and then fitting the abandoned area for silt deposition and drainage of the desilted water. The feasibility of such a plan depends very much on the ability of the Government to relocate and raise many towns and villages, giving each suitable protection. Since this process would be continuous and accompanied by constant difficulties with the population, the writers have hesitated to urge the adoption of such methods.

Colonel Dent's analysis of the silt inflow, deposition, and outflow for the Shanchow-Chinchang reach is interesting. However, if there is an excess of silt leaving a reach during a certain period, it is not certain that this excess is due chiefly to tributary inflow. A considerable portion may have been eroded from the river-bed.

The writers agree that for the reach from Shanchow to Mengtsin there will not be much difference in the silt inflow and outflow and that whatever difference there is will be due to tributary inflow; but for the reach from Mengtsin to Chinchang the case is different. Here both deposition and erosion are going on at a rapid rate, especially during the flood season. The net result is a slow but steady rise of the bed and foreshores. Referring to Tables 7 and 8, it will be seen that for the two years 1934 and 1935 the following volumes entered and left at Shanchow and Chinchang (in cubic feet of silt):

Entering at Shanchow	96 174 900 000
Leaving at Chinchang	98 378 890 000
Excess leaving at Chinchang	2 203 990 000

—or, 82 000 000 cu yd. From silt records of the Lo Ho and Chin Ho for 1934 and 1935 (incomplete during the low-water season), it has been computed that these two rivers carried approximately the following silt volumes (in cubic feet):

Year	Lo Ho	Chin Ho
1934	325 000 000	280 000 000
1935	1 750 000 000	770 000 000
Total	2 075 000 000	1 050 000 000

The total of the two is 3 125 000 000 cu ft, or about 115 000 000 cu yd. Taking into account other small streams which brought silt into the reach, one may say that as much as 150 000 000 cu yd of silt entered the Shanchow-Chinchang reach from tributaries during the 2-yr period, 1934–1935. Hence, only 68 000 000 cu yd of silt seem to have been deposited between Shanchow and Mengtsin due to the steep slope. This differs considerably from the value of 500 000 000 cu yd computed by Colonel Dent. Unfortunately, he did not have the Lo Ho and Chin Ho data to guide his judgment.

Colonel Dent finds it difficult to reconcile the 52 000 000 000 cu ft of silt entering the diked section at Chinchang in 1934 (and a similar amount in 1935) with the estimated 22 000 000 000 cu ft passing Litsin at the head of the delta under a regulated condition. Both 1934 and 1935 must be regarded as more than average flow and silt years, however. The yearly average silt volume passing Chinchang has been estimated by the Yellow River Commission at 35 000 000 000 cu ft. Furthermore, the average value of 22 000 000 000 cu ft passing Litsin was based on the Shantung settling basins being in operation; but it is quite possible that the silt volume reaching the delta every year may be greater than 22 000 000 000 cu ft. If this proves to be the case, the lower course will likely deteriorate more rapidly than estimated. The aim of the regulation must be to attempt as nearly as possible to bring a silt quantity to sea which will bear such a relation to the silt deposition up stream that neither the one nor the other deposition will be out of step and thus unduly accelerate the superelevation of the river's course along that reach.

With regard to the former rise of the river-bed across the plain, the writers have mentioned 3 ft per century as an average value, having checked a similar figure by Mr. Freeman referred to by Colonel Dent. However, this value has been based on the plain outside the dikes as reference; but, obviously, since the plain also has had silt deposited on it, the actual rise, with reference to a fixed plane, must be greater. If, as has been stated, the average yearly silt inflow at Chinchang has been 35 000 000 000 cu ft and the outflow into the delta 15 000 000 000 cu ft, 20 000 000 000 cu ft per yr have been left behind along the diked channel, and on the plain, as a result of dike breaks. The entire river channel has thus risen with the plain, but also slowly above the rising plain.

Assuming that 70% of the silt that has been left behind has been deposited in the up-stream 200 miles of the river's lower course (in the channel and on the plain), there will have been deposited in 100 yr about 1 400 000 000 000 cu ft of silt in this locality. From personal investigation the writers know that practically all of the silt that flows out on to this plain through dike breaks becomes deposited within 30 miles of the dike lines. A section through the deposition normal to the river's course will have approximately the form of a trapezoid, the top being the distance between dikes and taken as 5 miles and the base as 65 miles. Deducting 85 000 000 000 cu ft for the 3-ft rise of the channel over this 200-mile stretch leaves 1 315 000 000 000 cu ft of silt deposited within this section whose height is computed at approximately 6.7 ft. Adding to this the former estimate of 3 ft gives a total rise in a century of nearly 10 ft with reference to a fixed plane. As the deposition is not regularly distributed along the river's course, there will be some variation from this average depth.

It is generally during super-floods, such as in 1933, that vast quantities of silt become deposited on the plain. During that flood alone from 60 000 000 000 to 80 000 000 000 cu ft of silt must have found its way to the plain. Following the break near Tungchuang in 1935, the silt volume deposited on the plain was estimated at 15 000 000 000 cu ft. Added to another large quantity that escaped through breaks at Kuantai the same year, probably as much as 20 000 000 000 cu ft of silt was deposited on the plain outside the dikes in 1935. In 1934, through the Kuantai breach, another 15 000 000 000 cu ft of silt reached the plain. During these three years alone, from 90 000 000 000 to 100 000 000 000 cu ft of silt must have been added to the deposits on the plain. None of this went farther than 30 miles from the dikes.

If the calculation for the rise of the plain and the river channel is further examined, it will be found that only 20% of the volume left behind appears to be deposited between the dikes, and the remaining 80% is deposited on the plain outside. In view of the foregoing estimates of silt volumes which are known to have flowed out on to the plain, this is not a surprising deduction. It is an approximate calculation, but the result cannot be materially altered even if the dike distance and the deposition limit away from the dike lines are changed 25% either way. It means that approximately 3 000 000 000 cu ft of silt are deposited along the river channel between the dikes every year, and this quantity is a measure for the efficiency of the river channel, as it has existed in the past, to transport silt.

Colonel Dent asks what will happen if the dike distance is narrowed and the dikes strengthened so as to make breaks improbable. Until river-laboratory research work has been conducted to clarify the river's silt action for wide and narrow dike distances, and for different widths of channel under various conditions of discharge, the writers are not prepared to make any definite statement of opinion. It does not seem reasonable, however, to expect a deterioration in the river's capacity to transport silt if the channel is regulated and the dike distance is adjusted so as to give the greatest transporting efficiency for silt. With regard to the 80% silt quantity (which, under existing conditions, is deposited on the plain outside the dikes), the writers have recommended settling basins in Western Shantung, and they have also strongly advocated soil-erosion control measures in the up-stream loess areas in order to reduce, gradually, the silt masses in the river's flow. They realize, however, as suggested by Colonel Dent and Professor Lane, that it may be necessary to have another silt-depositing basin along the up-stream reaches of the river's diked course to be used until the up-stream soil-erosion control program becomes effective. They do not believe, however, that it would be wise, at the outset, to advocate a system of controlled silt-depositing reservoirs on the plain, as this would be likely to stir up strong opposition that would be very difficult to overcome. It could only be done in case the soil-erosion control should prove an absolute failure, and after the delta has advanced so far as to threaten to make the entire lower course untenable. There are social aspects to the problem that add to its complexity.

Colonel Dent wishes a silt-depositing reservoir west of Tungchuang mainly for the purpose of getting rid of the coarser silt particles so that the river channel down stream, where the slope is flatter, will be able to convey the silt. Theoretically, of course, this is correct. The writers deal with this point in their comments on the discussion by Professor Lane and merely wish to state here that west of Tungchuang the natural conditions for silt deposition are not so favorable as east of that place. The silt-settling basins proposed by the writers are so located as to require little construction work to create them and to bring the clarified flow back to the river. A deposition basin, however, is possible immediately east of the Peiping-Hankow Railway, on the north side of the river. The land is low and unproductive at this point, and the population not dense; but costly construction works are required. So very important is the problem of taking care of excess silt that further studies, both in the field and the laboratory, seem necessary for a satisfactory solution.

With regard to the danger of the channel being plugged by silt after a freshet, the writers' opinion is that there may be a danger of plugging during a freshet if the flow is exceptionally silt laden. The high elevation of the old channel prior to 1851, east of Hsüchow, where Mr. Chatley has had occasion to observe it, is probably not due to any plugging after the occurrence of the 1851 breach. Most likely it is due to the same prolonged silt action that has been building up the channels in which the river has been flowing. When a breach occurs, the abandoned channel quickly tends to become choked at that point, and it is only the nearest 15 to 20 miles that are seriously silted up by the rapidly diminishing flow. This was especially noticeable after the Tungchuang breach in 1935. Three months after the break occurred at this point there was almost no flow passing down the abandoned river channel. Cross-sections showed that 15 miles below the break the bed of the channel had retained practically its former elevation and shape.

Mr. Chatley questions the value of 2 500 000 cu ft per sec as a probable maximum for the Yangtzekiang at Ichang, 400 miles up stream from Hankow. One of the writers has had an opportunity to investigate the probable maximum discharge of the Yangtzekiang just below Ichang and has found that it is possible for the aforementioned discharge to occur. The reason the lower stretches of that river do not show a higher discharge is the existence of the two enormous lakes, Tungting and Poyang, which act as regulators for the Yangtzekiang. Usually, when the flood is heavy from the up-stream regions, there are also dike breaks which further aid in regulating the flow. Another moderating factor is found in the fact that the tributaries to these lakes are in flood late in June, whereas, the most serious floods from the main upper river come in late July or August.

In regard to the Yellow River delta surveys, both the British Admiralty and the German land surveys have astronomical positions close to the coast in that region. These surveys have been checked by the more precise surveys made by the Yellow River Commission. Positions of the more important villages have been compared and found to agree reasonably well, especially in latitude. The writers believe, therefore, that the estimate they have made of delta advance is fairly reliable.

Mr. van der Veen complains that the writers have not given due credit to certain previous writers on the Yellow River, notably his countryman, Mr. Fijnje van Salverda, who issued a memorandum in 1887. Lack of space made it impossible for them to devote any considerable portion of the paper to a discussion of former writings, however interesting this might have been. They had so much new material to discuss that they referred the interested readers to Mr. Freeman's paper on "Flood Problems in China"[3] where references to, and discussions of, works on the Yellow River by former writers could be found. The writers wrote entirely from their own knowledge and experience with the river itself and only referred to such works as, to them, seemed of sufficient importance to be of distinct value in adding to the hydraulic knowledge of the river. They regard the hydraulic laboratory experiments which were made in Germany for the Chinese Government (by a collaboration of Chinese and German engineers under the leadership of Prof. H. Engels), as a distinct contribution toward improving the knowledge of the Yellow River in spite of the fact that they were made without simulating the conditions of the Yellow River too well. When the results of these experiments are compared with those which eminent engineers such as Freeman and Franzius expected from their narrowing in of the dike distance and river channel, then it must be agreed that the experimental results gave "some startling indications."

Mr. van der Veen is correct in urging better dikes and better dike protection for the immediate future, pending a complete solution of the Yellow River problem. This is one of the practical aspects of the situation wherein all western engineers conversant with it agree. In fact, the inadequacy of the dike system, its low factor of safety in many places, and its haphazard location has brought adverse criticism from nearly every investigator who has had the opportunity of making a personal inspection.

The flood problem of the Yellow River does not end merely with strengthening the present dikes, however. To declare that it is merely a diking job is to close one's eyes to the real issue. Mr. van der Veen feels that the writers have explored too many angles of the problem and mentions "seeing a few particular trees but not the forest of which they form a part." He would limit the problem of Yellow River control mostly to a program of strengthening the dikes and banks where the current impinges on them. The writers believe that the problem must be attacked from several directions and that an adequate dike system is only a part of the remedy needed. The Yellow River problem has its roots in the most stupendous and rapid geological transformation process which is taking place on this planet—a process which has been created, for the most part, by human ignorance and carelessness. Soil has been stripped of the cover of vegetation that held it in place, and food-producing plants with less soil binding properties have been put on all these highlands that required careful treatment. The cultivation of these crops induced erosion which has continued without abatement for centuries. To repair the enormous erosion damage that has already been done is impossible; but it may be possible to retard it appreciably, if not entirely to arrest it. This will be the work of decades; and, in the meantime, ways and means must be found to control the floods and the silt masses that make the otherwise attractive and fertile Great Plain of North China such an insecure place in which to dwell. Most likely the Yellow River will always have a silt problem which will be reduced gradually in importance with the development of erosion control. The laws of silt transportation, as they apply to this river, will eventually be determined in suitable field laboratories and will give the river engineer this added power not possessed by the mere dike builder.

The writers have not recommended that dredges be introduced without mature consideration. When the channel has been regulated, the use of dredges may mean much toward a prolongation of its life. How far out into the delta it will be practical to use dredges only experience can prove. This equipment will have to be of a different type than the antiquated bucket dredge, which, due to bad seamanship, ran on a silt bank, capsized, and was buried in silt at the mouth of the river in the 1890's. That feat should not be cited as a warning to keep dredges from the Yellow River. Unlike the Mississippi, the Yellow River scours on rising stages. If dredged cuts are kept open through crossings immediately before the flood season begins, it may result in the river scouring a channel deeper than otherwise. It is likely that the low-water season's bed-load will be induced to progress down stream more efficiently by dredging cuts through bars which act as obstacles, tending to silt up the channel as a whole. A judicious use of dredges may prove to be the turning point in preventing the river from raising its bed due to other causes than prolongation of the delta.

Mr. van der Veen believes that the soil condition of the river banks has little to do with groin spacing. In the case of very long groins this is true; but for short groins the condition of the soil is an important consideration in spacing. This has been the experience of engineers on the Yellow River.

Mr. Jarvis calls attention to the fact that the Wei Ho is the greatest flood producer and silt carrier of the tributaries and hence requires special attention. In Fig. 1, the writers have shown possible dam sites for detention basins on the upper Wei Ho in Kansu, and also on the King Ho and Pei Lo Ho in Shensi, these latter being feeders of the Wei Ho. Such detention basins may be of great assistance in smoothing out crest flows. It is also in this region that, eventually, extensive soil-erosion control work must be constructed, as it is one of the critical parts of the Yellow River system, especially in the matter of silt flow. The writers have not drawn more attention to the Wei Ho because they believe the main river to be in more immediate need of control. The Wei Ho silt is of such extreme fineness, being mostly of clay composition, that it will not cause the same difficulty along the diked channel as the silt from the main river. Therefore, corrective measures on the drainage area between Tungkuan and Tokoto in Suiyuan should take precedence over similar measures on the Wei Ho drainage area.

The writers had suggested only one auxiliary flood channel—the Tu Hai Ho—or one in its general vicinity. Hills on the southeast bank prevent the location of a similar channel on that side of the river from the old Grand Canal crossing to a point a few miles up stream from Lokou. It is possible, however, to have an auxiliary channel to the south of the river from a point near Lanfeng, just east of Kaifeng, to Tungping Lake and then through the Po Ho to the main river. As Mr. Jarvis suggests, such channels might aid in maintaining capacities in the main river at critical times. In this vicinity there are areas that could take large silt storage in filling depressions.

The writers are highly appreciative of the careful study given this subject by Professor Lane and share with him some of the anxieties he has in the matter of silt transport and disposition. It is agreed that, aside from handling the flood waters and routing them to the sea, there is the closely allied problem of controlling the silt or sediment stream. He is entirely in accord with the writers in emphasizing the need for the further development of laws governing the transportation of sediment. Professor Lane's discussion is especially valuable since he is able to write not only with a personal knowledge of Chinese river conditions, but also with years of experience in the study of silty rivers in both field and laboratory. Some of his field work has been in the Huai River valley south of the Yellow River.

Professor Lane intimates that a possible danger in a flood-control and silt-control detention basin is that the silt concentration is likely to be a maximum when the outflow from the basin has become nearly that of the natural stream. Hence the Yellow River course through the plain may be in danger of choking. Opinions may differ both in regard to the time of maximum silt concentration in the outflow (see Fig. 20) and the possibility of choking. Since it is not possible to solve these problems by analytical deductions, the writers have recommended that they be solved by laboratory experiments, or, preferably, on small, silty streams such as may be found in Southern California or Arizona.

In this connection actual field data from the Yellow River for August, 1934, show that the diked river is capable of conveying a flood of about 185 000 cu ft per sec, with an 11% silt load, through the entire length of its lower course from Taochengpu to the sea without injuring the channel to any marked degree (see Item 1 in Table 6, Table 7, and Table 4, August 9–20, 1934). Attention is called to the controlling influence of the section between Shanchow and Chinchang on the silt concentration. It is the Mengtsin-Chinchang section of this reach which acts as a temporary storage reservoir when the silt masses become excessive. The next depositing area under present non-regulated conditions is between the 1851 break and Kaotsun near the Shantung border. These two natural storage regions for silt seem, so far, to have prevented the silt concentration in the diked river below Kaotsun from exceeding 12½%. Mr. Freeman records about 10% in 1919 near the Grand Canal crossing. The values for August, 1934, in Table 4, are the highest recorded by the Yellow River Commission for the lower diked river. It seems quite possible, after the channel has become regulated, that discharge of 200 000 cu ft per sec may convey a silt load of nearly 20% without serious deterioration of the channel.

If the Palihutung or Sanmen detention basin project were to be completed and the diked channel regulated, one might expect (see Figs. 19 and 20) that the maximum silt concentration in the outflow would not exceed 40%. (It may even be possible to keep the maximum silt percentage lower than this by gates whereby the stages in the basin could be controlled and excessive silt scour from the basin thus reduced.) Reasoning from what occurs at present along the down-stream channel, one may assume further that the silt concentration in the outflow would be reduced down stream to about 20% by temporary storage between Mengtsin and Chinchang and to 17 or 18% at Kaotsun, from which place the flow would continue with the same silt load right through the diked channel. There might be some deterioration of the diked channel during exceptional floods having very high silt loads; but it seems scarcely reasonable to expect that the diked channel at any place would become choked and the flow sent over the dikes, since in a regulated channel the silt would tend to become uniformly deposited all along the channel. It is also very probable that the clear outflow from the basin, preceding the scour period, would remove considerable silt from the channel between Chinchang and Kaotsun, the same reach where refill would later take place, thus further reducing chances of choking. Since not all large floods are as heavily silt laden as that of August, 1933 (of which Fig. 20 is an actual record), the channel will again improve in time.

To interpose another silt-depositing reservoir near the up-stream end of the diked course is scarcely advisable although it may be done in case of need. To arrange for such a reservoir would be a formidable technical problem. If, in its simplest form, it is made as a lake, through which the river flowed all the time, depositing most of its silt there, it would become silted up rapidly, even if it had an area of 1 000 sq miles. If it were meant to receive the silty flow only during the periods of heaviest silt concentration, control works would be required both across the main river channel and on the side into the reservoir, as well as for the outlet back to the river channel.

It has been contended several times, in the discussion, that the change in slope along the diked channel will affect, materially, the river's capacity to transport a heavy silt load. This may not necessarily be the case. Field studies made of the Yellow River indicate that slope changes within the limit of those which exist along the diked course are not sufficient to detract seriously from the river's capacity to carry silt. The slope which will begin to affect silt transportation seriously will, most likely, be found to be considerably flatter than those which exist, especially after the channel has been regulated. Of course, there are limits for discharge and silt load beyond which the existing slopes will begin to take effect; but the writers believe that these limits, due to the fineness of the silt, lie much higher than on other rivers—hence, their optimism in regard to the non-choking probabilities in case flood-control and silt-control detention basins should prove feasible.

Under a system of flood-control and silt-detention basins west of the plain, there is the objection that nearly all of the silt will be deposited in the sea and rapidly make the lower diked course untenable. If soil-erosion control in the loess areas is vigorously pursued, however, this objection may not be serious, since the erosion control may be expected to bring imposing results within three or four decades. Nevertheless, the possibility exists that such control may not be sufficiently effective, and the problem arises of how else to handle the silt. Professor Lane pointedly draws attention to this and suggests three methods:

1. Keeping it in place on the water-shed (may not be very effective);
2. Taking part out of the river channel and storing it on the plain; and
3. Carrying a part out to sea and depositing it on the sea floor.

The writers concur fully with Professor Lane in these suggestions, but at the same time they maintain that it is of paramount importance to regulate the channel, as without regulation it will be impossible to enforce any other control. Nothing can be done with a river which is likely to break loose anywhere and which wanders at will over a broad strip of land within irregular lines of dikes spaced excessively far apart. The silt problem must be handled quantitatively, and this can be done first after the channel has been regulated. It must be determined how much silt goes to the land, how much is left between the dikes, and how much goes to the sea. These quantities should be so proportioned that they will give the longest life to the entire diked channel. To obtain the desired uniformity and quantitative control of deposition in channel, outside areas, and sea, it is essential that the entire channel be so regulated that there is no chance for any outflanking of the control works. The outflanking of the Yung Ting Ho diversion works in 1933 and 1934 was due to the fact that the river up stream was unregulated. This and other illustrations of costly gambling with silty rivers in North China remind engineers of the prudence of stabilizing and regulating these channels.

It has been suggested that the writers might have considered the matter of silt disposal more fully in their recommendation for control measures. To do so would have meant, evidently, a quantitative appraisal of silt disposal. Data for doing so, unfortunately, are still insufficient. Professor Lane suggests certain principles along which such silt disposal should be guided, but at the same time recommends laboratory research for quantitative determinations. To this the writers agree, and here the matter must rest for the time. With China at war there seems little opportunity of this research work being undertaken in that country. Possibly a way will be found to solve some of these problems in the United States so that a comprehensive control of the Yellow River will be planned with greater assurance that the element of chance has been removed to a very large degree.

The proposals of Mr. Higgins have been answered in replies to previous discussions. The writers believe that they have remarked fully enough on the possibility of letting the river "handle its own problem." They are convinced that more control, rather than less, is essential, especially where there is such a dense population to be considered. Resourceful though they be, the Chinese farmers need direction in matters such as control of Yellow River floods, because these come as great avalanches of water surcharged with mud. Too long, the people of China have been victims of these river "dragons." It is time for the entire engineering profession to give the very highest service in its power to bring this river under control. It is a task for hydraulic engineers with years of intimate river experience.

THE RISK OF THE UNEXPECTED IN SUB-SURFACE CONSTRUCTION CONTRACTS

BY OREN CLIVE HERWITZ,[1] ESQ.

WITH DISCUSSION BY MESSRS. ALONZO J. HAMMOND, FREDERICK W. NEWTON, DAVID A. MOLITOR, F. B. MARSH, EVAN S. MARTIN, C. MAXWELL STANLEY, FRANCIS J. MORGAN AND FREDERICK C. ZEIGLER, LAZARUS WHITE, T. KENNARD THOMSON, CARROLL A. FARWELL, AND OREN CLIVE HERWITZ.

SYNOPSIS

In the early days before the development of a technique for preliminary underground exploration, it was customary for the contract to provide that the risk of the unexpected should fall on the contractor. Broadly worded contract clauses took the place of scientific and careful investigation. This practice often resulted in a higher total cost to the owner, since contractors, perforce, added an arbitrary sum to their bids to cover possible difficulties (1(*a*));[2] that is, the owner passed on the risk to the contractor and paid a substantial premium for this insurance against loss.

Modern standards of sub-surface investigation, as detailed in the Society's Manual of Engineering Practice No. 8 (1), have eliminated much of the costly uncertainty involved in underground construction, with corresponding benefit to owner and contractor. Indeed, the cost of supplying the contractor with complete data on subterranean conditions will generally be less than the sum contractors would charge for blindly assuming all risks.

Nature, however, often shows a whimsical unconcern for Man's data; a careful and complete preliminary investigation may not always forecast actual subsoil conditions accurately. In that event, the parties to the contract often disagree as to which must bear the loss. Even an agreement carefully drawn along the lines suggested in Manual No. 8 (1) may yet leave room for reasonable men to differ as to its interpretation; and, when amicable adjustment of the dispute is not effected, it is more than likely that recourse will be had to the Courts.

Experience in this type of litigation shows that emphasis is placed on carefully worded specifications, often with results expensively significant to one

party or the other. A judicial ruling may result in an unexpected assessment against the owner or in wrecking the contractor.

This paper shows how reports of borings and similar data may return to plague both owner and contractor, even when given in the utmost good faith and with careful attention to the best modern practice. There should be a clear "meeting of the minds" in the perfect contract. It is necessary, therefore, that both parties to the contract understand the extent of the risks they are assuming, so that the hazards of litigation may not be added to the still substantial uncertainties of the subsoil.

BORING DATA

In Manual No. 8 it is suggested that variations in subsoil conditions, revealed during the progress of the work, shall not entitle the contractor to additional compensation, unless the variance is considerable and the error in the preliminary boring data is firmly established (1(*b*)). However, extra compensation has been allowed by the Courts even without specific evidence that error was made in gathering the preliminary information.

In one case (2), the contractor had agreed to excavate a by-pass for Oklahoma City, Okla. Boring and sounding records appended to the contract led the contractor to believe that the material to be excavated consisted of a quantity of earth and dirt with a small quantity of rock. There was no language in the contract purporting to absolve the City from liability should the indications of the borings and soundings prove inaccurate. The contractor bid a unit price per cubic yard for "all excavation," which was to "cover the excavation of all earth of whatsoever nature down to the grades and lines as shown on the plans." Instead of the small quantity of rock indicated by the preliminary tests, about 60 000 cu yd were found, and suit was brought to recover the additional cost of excavating it.

The State Supreme Court of Oklahoma held that the contractor was entitled to recover, stressing the combined significance of two facts: (*a*) That the contractor was led to believe from the records of borings and soundings "that there was no rock to be encountered except in negligible quantities"; and (*b*) that the price bid, from the restrictive language of the specifications, merely covered the excavation of earth. The word, "earth," it was declared, did not include rock (3); therefore, the excavation of rock had not been "contemplated nor contracted for," and should be treated as extra work.

If, unlike the foregoing case, the language of the contract is broad enough to embrace removal of materials not shown by the borings (4), contract provisions designed to shift the risk to the contractor should the borings prove misleading are frequently effective, particularly in the absence of evidence that serious error was made in making the tests. Thus, it has been held that if the owner "does not warrant the indications of the borings to be correct," and if the contractor agrees that he shall have no claim "should the character and extent of the various materials be found to differ from what is indicated," owner responsibility for the unexpected is averted (5).

A similar ruling was made in a case in which the contract stated that there was no express or implied guaranty as to the accuracy of the borings and soundings, and directed each bidder to place his own interpretation upon the soundings and borings made by the City in forming his opinion of the character of the materials to be excavated (6).

The State of New York includes in its contracts a disclaimer clause which has proved an almost impenetrable barrier against claims based on unexpected sub-surface conditions. A leading case in point is Foundation Company *vs.* State of New York (7), where a recovery was denied in spite of the fact that the borings incorrectly indicated the elevation at which bed-rock would be encountered. The contractor there had agreed that he would make no claim against the State "because any of the estimates, tests, or representations of any kind affecting the work made by any officer or agent of the State, may prove to be in any respect erroneous." This disclaimer clause is ineffective, however, where fraud is proven (as discussed subsequently), and also where the extra expense incurred is due to a subsequent act of neglect or default on the part of the State (9).

Disclaimer clauses have even been held to cover a case in which the borings were interpreted incorrectly by the owner's engineer. The evidence in that case (10) was that the engineer's error was due to his ignorance of the wash-boring technique; the indications of hardpan were not recognized. The decision holding against the contractor's claim rested largely on a contract clause stating that the borings were exhibited to the contractor so that he could form his own judgment without implying any guaranty on the part of the owner as to their completeness or correctness. The Court held that, under this clause, an honest mistake would not justify a recovery unless it rose to "that degree sufficient to brand it as the equivalent of fraud or bad faith." A similar ruling was made in another case (11) where the contract stated that the borings were not guaranteed to be absolutely correct.

No disclaimer clause can force the contractor to assume the risk of deceptive borings, however, if the information given is known to be incomplete or misleading. The well established doctrine that no man may contract against his own "fraud" (12), strikes down any attempt on the part of the owner to escape liability for "unexpected" subsoil conditions. Although the principle is undeniably sound, difficulty lurks in determining just what facts will justify its application.

A well known case arose from a contract with the United States Government for the construction of three locks and dams on the Warrior River, in Alabama (13). Borings met "obstructions which, from the particles broken off and floating to the surface, would indicate that they might be logs." When this happened the drill was moved elsewhere until a place was found into which it would penetrate. The evidence of buried logs was not noted on the boring plans because the Government's engineer did not consider them of sufficient importance to be so recorded.

Although the Court found that this was an honest opinion and that there was no conscious intention to conceal material information from bidders, the contractor was permitted to recover the additional cost of uprooting stumps, buried logs, cemented sand and gravel, and sand-stone conglomerate, none of which was indicated on the borings. The extent to which the Court's decision was influenced by the statement in the specifications that "the material to be excavated, as far as known, is shown by borings" is not apparent, but it is significant that, in its opinion, the Court italicized the words, "as far as known" (14). In any event, it would seem that the engineer's failure to note a significant detail on the boring plan may have an expensive sequel.

Even the broad disclaimer clause included in New York State contracts has been held impotent to prevent recovery by the contractor when material information has been knowingly concealed. In one case (15) the State had conducted earlier boring and sounding tests which suggested the presence of hardpan, but the results of these preliminary explorations were not disclosed to bidders. Instead, they were given a later series of wash-borings which did not show hardpan. Although the State's engineer testified that the earlier borings were not disclosed because, in his honest opinion, they were not as reliable an indication as those that were shown, the contractor was allowed to recover the additional cost of excavating hardpan. Recovery was also allowed in another case where the statute authorizing the construction of the New York State Barge Canal required the State to give bidders accurate information (16).

In still another case (17), it appeared that the Passaic Valley Sewerage Commissioners had contracted for the construction of a subterranean and submarine sewerage tunnel. A series of borings had been made and the results tabulated on a set of plans appended to the contract. These findings signified that under the waters of New York Bay the material to be excavated consisted of a layer of mud; below that a layer of sand and some boulders; and, beneath that, a "cemented Triassic formation."

On these data the Commissioners entered into a contract with a party which, after completing only part of the work and failing to find the "cemented Triassic formation," abandoned the job. The Commissioners then entered into a contract with a second party on exactly the same data previously used. Again, the elusive rock formation was not found; again, the contractor abandoned the work.

In re-advertising the contract for the third time the Commissioners, now apparently doubtful of the accuracy of the borings, added a note to the contract stating that the borings were "supposed to be approximately correct, but should they be found to be otherwise the contractor shall have no claim on that account, it being expressly understood that the Commissioners do not warrant the plot to be approximately correct." The contract was awarded, and for the third time the "cemented Triassic formation" was not found; instead, gravel, quicksand, bull-liver, boulders, and other pervious materials were encountered. This time the contractor stopped work and brought an action for damages. A verdict for the plaintiff was affirmed by the Circuit Court of Appeals. It was held that the self-exonerating note appended to the boring plans was ineffective to relieve the defendant from liability, inasmuch as the defendant knew from its two previous experiences that the borings were misleading (18).

In another case, it appeared that a plan of preliminary borings was included in a contract to construct a section of the Lexington Avenue Subway in the City of New York, N. Y. (19). The borings, although "not guaranteed," indicated that the tunnel was to be constructed entirely through solid rock, and the contract drawings were obviously based upon that supposition; but the drawings also contained a notation that "if rock is not encountered, the design of the side walls and floor will be modified." For a considerable part of the distance traversed the contractor met soft earth and mud that required a pneumatic method of tunneling, and to recover the higher cost of this type of construction an action was commenced. In allowing a recovery the Court emphasized the fact that on file in the office of the Public Service Commission there was a copy of the "Viele" map which showed that in earlier times a creek had crossed the line of work at the point where soft earth and mud were found. From this, the Court stated, the engineers for the Public Service Commission should have expected that soft earth or mud would there be encountered. It was concluded, therefore, that the extra work was caused by conditions which should have been anticipated by the Commission, and could not have been discovered by bidders (20). Testimony that the map was also filed in the New York Public Library and was readily available for inspection by prospective bidders was apparently not considered of any significance in this instance. The ready availability of the allegedly concealed information, however, has been emphasized in cases denying recovery (21). Greatly stressed was the bidder's inability to make his own borings, since the sub-surface lay under a principal thoroughfare of the city (22). By the same token, the bidder's opportunity to make borings has been given equal importance in cases denying recovery (23).

Although Manual No. 8 (1*c*) suggests that boring data be included with the contract and guaranteed as to correctness, it also advises that "soil conditions between borings may be assumed by the contractor at his own risk." The distinction thus drawn between guaranteeing merely the nature of the subsoil within the limited area encompassed by the boring pipe, and not the subsoil throughout the entire site, is one that is not readily accepted by a Court of law. Judicial interpretation of a boring plan as being merely a statement of what was found where the borings were made is rarely encountered (24).

Fig. 1(*a*) represents a situation where bidders are merely advised as to the results of the boring tests at the place where the borings were taken. Fig. 1(*b*), on the contrary, constitutes a statement not only of the results of the borings, but also of what is to be expected elsewhere.

A notable exception to the judicial reluctance to distinguish between these two situations is the opinion of the Circuit Court of Appeals in litigation over the construction of a bridge across the Arkansas River, at Fort Smith, Ark. (25). The contractor sought to cancel his contract because he found quicksand unexpectedly and because he did not encounter the soft shale and soapstone shown by the borings. The only statement in the contract pertaining to the borings was that "the findings are as indicated on sheet number 2," which, the Court said, amounted to nothing more than a statement that the findings of the borings were truly indicated. In its opinion the Court considered the interpretation of borings in relation to construction contracts (26). It concluded that the borings were submitted merely as a bit of useful information, and not as a statement of sub-surface conditions generally to be expected throughout the site (27). There being no evidence that the results of the borings were not fully and fairly recorded on the boring plan, the Court held the defendant innocent of misrepresentation, and, accordingly, denied recovery.

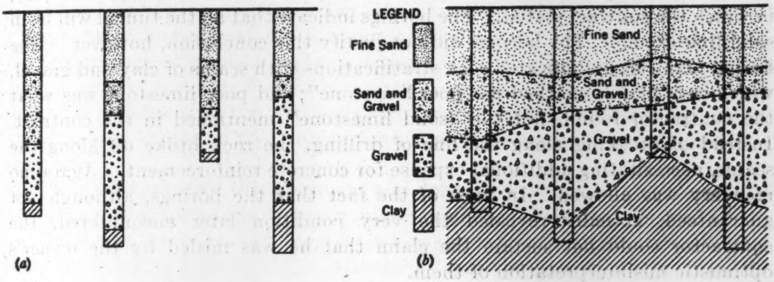

FIG. 1

This case eloquently illustrates to the two conflicting interpretations of a boring plan which Courts have been urged to adopt. Since the Court's understanding of borings is largely limited to what is testified before it by experts, irreconcilable decisions may be expected to continue as long as witnesses disagree.

OWNER INTERPRETATION OF BORINGS

In addition to a boring plan, the owner sometimes supplies his own conclusions as to what the borings show with reference to subsoil conditions throughout the entire site. Whether the owner thereby assumes any greater risk if his conclusion proves erroneous or misleading turns again on the Court's interpretation of the language used in the agreement. Thus, in a contract for the construction of a railroad bridge the contractor was directed to use a certain borrow-pit. The specifications stated that the borrow-pit was to be excavated to Elevation 655, except that no blue clay (which the borings indicated was approximately 15 ft below the surface) was to be taken (28). The contractor found the blue clay only 6.5 ft below the surface, and brought suit to recover the cost of obtaining additional fill elsewhere.

In the lower Court, the contractor won judgment on the theory that the railroad company had "falsely stated in the specifications that there was no blue clay in the tract nearer the surface than 15 ft"; but this judgment was reversed on appeal. The Appellate Court held that the lower Court had misconstrued the language used in the contract; the only statement made in the specifications was what the borings indicated, rather than what was the actual condition of the entire subsoil (29).

After constructing a lock and dam on the Ohio River up stream from Ashland, Ky., a contractor sued to recover the additional expense of removing unexpected logs, snags, and stumps, found embedded in the river silt. These obstructions were not indicated on the boring plan, and the contract contained a disclaimer clause (30). The evidence disclosed that an earlier series of borings were not even shown to bidders and that one of these borings had encountered a "log next to rock." Nevertheless, a recovery was denied in view of the broadly worded disclaimer clause (31).

An interesting variation on this theme was presented in a Missouri case (32), in which the contract stated: "The borings indicate that all the tunnel will be in solid limestone." The borings did not justify this conclusion, however. The boring plan clearly indicated rock stratifications with seams of clay and gravel, which were plainly marked as "poor limestone"; and poor limestone was what the contractor found, not the "solid limestone" mentioned in the contract. Instead of breaking along the line of drilling, the rock broke off along the seams, necessitating additional expense for concrete reinforcement. Again, no recovery was allowed. In view of the fact that the borings, although not guaranteed, actually revealed the very condition later encountered, the contractor could not sustain the claim that he was misled by the owner's optimistic misinterpretation of them.

Profiles and Cross-Sections

Instead of a boring plan, there may sometimes be annexed to the contract a profile or cross-section showing the elevations of the surface and underlying rock, or the general composition of the subsoil throughout the site. In this case, the contractor is presented with the owner's conclusions as to sub-surface conditions, sometimes without access to the preliminary information upon which they were based. Must the contractor bear the loss if the true situation is found to differ from that indicated on the plan?

Here, again, the language of the contract is generally the decisive factor. In one case a profile plan showed the location of a proposed sewer in relation to the existing surface of the street (33). Superimposed on this plan was a convoluted, dotted, line marked: "Probable surface of rock as shown by borings." The contractor had agreed, however, that if "the location of the rock be found to differ from what is indicated," he "shall have no claim on that account." During excavation, quicksand was encountered where the profile showed rock, and the contractor sued for the added expense thereby occasioned. Recovery was denied. The Court held that the contract clause was a disclaimer of warranty relating "expressly to the convoluted line which the plaintiffs claim constitutes a warranty of the true location of the rock."

It has also been held that if the specifications state that "the profiles are reasonably correct, but are not guaranteed to be absolutely so," honest mistakes made in observing and recording the results of the borings upon which the profile plan had been based, were not actionable (11). Similarly, owner liability was not imposed when the actual physical conditions, although different from the profile, were "obvious to any careful observer." For example, where it was a matter of common knowledge that a saw-mill had formerly occupied the site of the work, the contractor in one case (34) could not recover the expense due to logs that were not indicated on the profile. Recovery was also denied in a case (35) in which the contract stated that "levels of the rock at various points are shown approximately on the plans, but the bidder must satisfy himself of the accuracy of these and of the rock surfaces in general."

On the other hand, the use of the word, "approximate," in connection with the information given, is not always effective to prevent recovery by the contractor. This was demonstrated in a Virginia case (36). Bidders on a proposed contract to construct a bridge over the James River, near Richmond, were furnished "a profile of existing conditions," which showed a line marked "rock" extending across the bottom of the river. The successful bidder discovered rock at a much lower elevation than that shown on the profile and sued to recover the cost of additional earth excavation. The City of Richmond argued in defense that the words, "approximate" and "plus or minus," before the elevation figures on the profile were sufficient to excuse it from liability for the error.

The Court rejected this argument and permitted the contractor to recover. It was said that the words, "plus or minus" and "approximate," as used on the profile, served to cover only "negligible deviations from entire accuracy"; they were intended to express the idea merely "that the line as shown upon the profile was nearly, but not exactly, correct." Since the actual conditions departed so substantially from those pictured on the profile, the qualifying words were held inadequate as a defense.

A contract for the construction of a new coagulation concrete basin in Alliance, Ohio, incorporated a plan showing, in cross-section, the location of the basin in relation to the existing grade, signified by a wavy, horizontal line marked "approximate original grade" (37). From the scale of the drawing, the contractor calculated that a general average excavation of about 9 ft and a fill of about 9 ft would be required. He found, however, that the actual average excavation was only about 3 ft, and brought suit for the cost of obtaining the necessary additional fill elsewhere.

A verdict for the defendant City was reversed on appeal and a new trial was ordered. As in the foregoing case (36), the Court held that the word, "approximate," would not protect the City in the face of so substantial a discrepancy. The attempt to charge the contractor with knowledge of the error, on the theory that the contour lines on another plan revealed the inaccuracy, was also unsuccessful. Proof that bidders do not customarily compute excavation from contour lines was accepted by the Court as sufficient to "excuse the contractor for not discovering the mistake."

Recovery was allowed in a similar case (38) where the piers were to be built "to the line and elevations given on the plans" and excavation was to be "done to the lines shown." Recovery was denied, however, where the specifications stated that the plans showed "approximate grades for excavation," but where the contractor was also directed to carry the excavation "to the foundation lines and grades as shown on the plan, or to such increased depth as may be necessary to obtain a firm foundation" (39).

In still another case the contractor complained because rock was found nearer the surface than suggested on the profile (40). His attempt to recover the cost of excavating additional rock was unsuccessful. Here, again, the line on the profile was marked "approximate rock line" but the contractor had also agreed, under another clause, to bear "all losses resulting to him * * * because the nature of the land in or on which the work is done is different from what is assumed or was expected." The fact that the contractor had failed to protest upon discovery of the error was likewise deemed fatal to the claim (41).

The foregoing case (40) was later cited by the same Court when it refused to grant a contractor the cost of extra excavation required to reach bed-rock (42). This claim was based upon the fact that a cross-section showed the foundations of the proposed dam resting on bed-rock, which, from the scale of the plan, appeared to be all above Elevation 148. The plans were to be "considered as only approximate," and although it was necessary to go a considerable distance below Elevation 148 to reach bed-rock, no recovery was permitted.

In holding that this was a contract to rest the foundations on bed-rock wherever found, and not a contract to build "these piers with foundations at a certain depth" shown on the plans, the Court emphasized the fact that the contract included a contingent item of "200 cubic yards of caisson work below elevation 148." The inclusion of such an item was considered a clear indication that bed-rock might be found below Elevation 148. The following part of the Court's opinion has been quoted frequently (43):

> "A contract and specification may contain representations as to existing physical conditions. If so, a bidder may rely upon them, even though it be provided that he shall satisfy himself by personal inspection and investigation as to their truth, where because of time or situation such investigation would be unavailing. (Faber *v.* City of New York, 222 N. Y. 255); or statements may be made on which the bidder, because of the language of the contract, cannot rely. He may have agreed that he will not. Then if they are made in good faith he takes the risk of their accuracy."

In litigation over the construction of an East River bridge, the same Court had earlier held that a plan indicating the existing rock surface and showing caissons sunk into it, was a warranty as to the true position of bed-rock (44). However, the specifications contained the added limitation that "bids are based upon depth of excavation indicated on the plans," and that "if excavation deeper than that shown on the plans is required it is to be paid for" at so much per cubic yard. Bed-rock was found from 8 ft to 9 ft higher than was shown on the plan. In order that the top of the caissons should not protrude over the water level and create an obstacle to navigation, the contractor was directed to excavate deeper into the rock.

The defense was based on a contract provision which required that "the contractor must assume the responsibilities for the difficulties encountered in sinking the foundations to bedrock or into it to whatever depth shall be determined upon." In view of the other contract provision requiring payment for additional excavation into rock, the Court decided that the argued clause contemplated the assumption of responsibility merely for any "difficulties" encountered in excavating into rock, but not for the additional "expense" thereby occasioned!

SUB-SURFACE DESCRIBED IN CONTRACT

A statement describing the materials to be encountered may be incorporated in the contract. The form of the alleged representation in this case is the language of the contract, and not mere lines or symbols on a plan whose meaning may be doubtful. Typical is the well known case (45) based on a United States Government contract for the repair of a dam, in which it was stated definitely that: "The dam is now backed for about fifty feet with broken stone, sawdust and sediment * * *." Instead, the contractor found a log cribwork filled with stones, and sued to recover the consequent additional expense. The contract provision requiring bidders to examine the site and to satisfy themselves as to the nature of the work to be done was urged in defense. With this argument the Court was unimpressed. A recovery was permitted because "the specifications spoke with certainty as to a part of the conditions to be encountered by the claimants," and of them, it was said, "the government might be presumed to speak with knowledge and authority."

In another case (46), recovery was permitted because the specifications stated falsely that "the vitrified pipe line is mostly, and the tunnels are entirely, to be in soft shale rock."

A similar conclusion was reached in a case arising out of a contract to excavate a ship channel at the mouth of the Detroit River (47). The material to be removed was stated to consist of: "Sand, gravel and boulders, all in unknown quantities"; but a large part of the material proved to be limestone rock. For the consequent additional cost of performance, the contractor was allowed reimbursement.

A contrary decision was given in an instance in which the statement as to the nature of the sub-surface was qualified (48). The contract stated that: "Good gravel will be encountered in the excavation," but the contractor was also notified that if sufficient gravel was not found, equally good gravel would have to be furnished for making concrete. The contractor, not finding any gravel at all, sued for the cost of obtaining it elsewhere. The Court held that no representation had been made to the contractor that he would find sufficient gravel in the excavation for making concrete; on the contrary: "All that the specifications say is that some gravel will be found in the excavation. The language of the specifications put him upon notice and required him to make investigation, and having failed to do so he cannot be heard to complain."

Recovery was likewise denied where the contract stated that a supply of necessary stone "could be obtained at Union Spring [N. Y.], at 90 cents the cubic yard" (49). Before bidding, the contractor made no attempt to verify this statement and, later, when he discovered that the stone could not be obtained at Union Spring, he tried to rescind the contract and recover his deposit. The broad disclaimer clause found in contracts with the State of New York, to which reference has been made heretofore, was cited by the Court in support of its conclusion that the contractor was not entitled to rely upon this statement as to source of supply.

In a very similar case, however, the clause was held impotent as a defense to the contractor's claim for the additional cost of obtaining stone at a place other than that mentioned in the specifications (50). Before bidding, the contractor had inquired at the place named in the specifications and was told that the stone was available. Later, when he sought to purchase the material, he discovered that the person in possession had no legal right to sell it, and thus he was forced at added expense to go elsewhere.

Having done everything possible to verify the statement and having found that, apparently, it was true, the contractor was deemed entitled to rely upon it; whereas, in the preceding case (49), recovery was denied because investigation by the bidder would have disclosed the error. Thus, in the face of contract disclaimer clauses, investigation seems to be the wisest course.

As has already been shown in other types of cases, however, exonerating language in a contract is unavailing if the representations made are knowingly false. This was the situation presented in a contract which stated that "the material to be removed is believed to be mainly mud, or mud with an admixture of fine sand, except from Station 54 to Station 55 plus 144 * * * where the material is firm sand and gravel or cobbles" (51). The "accuracy of this description" was expressly not guaranteed and bidders were enjoined to decide for themselves the character of the materials to be handled. The description presumably was based on preliminary borings made by the Federal Government, which also were included in the contract with the statement that:

> "No guarantee is given as to the correctness of these borings in representing the character of the bottom over the entire vicinity in which they were taken, although the general information given thereby is believed to be trustworthy."

Upon finding a heavy compacted material instead of mud and fine sand, the contractor discontinued operations and sued to recover the value of the work already done. It was shown that the Government had encountered an impenetrable material during preliminary borings and had not noted this fact on the plans. Recovery was allowed by the United States Supreme Court. The decision apparently turned upon the fact that the Government's assertion of "belief" as to the nature of the material was knowingly false, in that it was contrary to other information in its possession. (Compare this statement with that in Pearson *vs.* State of New York (8) in which the use of the word, "expected," was considered to be merely a statement of "hope or expectation" and not a "positive agreement or warranty.") Emphasized, too, was the fact that before work was begun, Government engineers had inspected the contractor's plant and equipment and approved it, knowing that it was suitable for dredging only the materials stated in the specifications.

Frequently, the statement or representation is not made part of the written contract. When such information proved incorrect, recovery was denied in an early case (52). The Court declared that a statement of the expected nature of the sub-surface was a mere expression of opinion "with reference to matters equally within the power of both of the parties to the contract to ascertain and determine for themselves," and that the failure to include this statement in the written contract indicated that the parties did not regard it as material.

IMPLIED SUBSOIL REPRESENTATIONS

It has occasionally been claimed that a plan, or the quantities stated in an engineer's estimate, or the methods prescribed for doing the work, led the contractor to believe that a certain type of sub-surface would be encountered. Such attempts to "spell out" an implied warranty have rarely been successful.

Plans.—In litigation over a contract to construct a sewer, it appeared that a plan showing the work to be done bore certain dotted lines which the testimony showed "was the usual manner of indicating an existing sewer" (53). The contractor claimed this authorized him to assume that there was such a sewer and that it would drain off all water flowing into or accumulating in the excavation during performance. In fact, no such sewer existed. An action was brought to recover the cost of keeping the trenches dry with pumps. Recovery was denied because of contract provisions requiring the contractor to keep all the trenches free from water while the excavation or the construction of the foundations and sewer was in progress. This provision negatived the idea that an outlet for water was to be supplied to the contractor by any existing sewer (54).

This ruling was repeated in an almost identical case (55), in which the contract also contained a similar clause requiring the contractor to keep the excavation free from water. In its opinion, the Court observed that, even if there had been a warranty that a sewer existed, there was certainly no warranty that it would be "fit and suitable for drainage."

In 1899 the City of New York entered into a contract to demolish the old reservoir at Forty-Second Street and Fifth Avenue to clear the way for the construction of the New York Public Library (56). Annexed to the contract was a plan which indicated the dimensions of the old reservoir walls, the angle of the slope, and the extent of the excavation and fill to be made. It did not, however, "show the quantity of material to be removed in removing the walls and foundation of the reservoir, or the quantity of this material that might be utilized upon the site for the filling required by the contract." The contractor asserted that these quantities could be calculated from the plans on the assumption they were correct and drawn to scale. The plans were inaccurate in that they indicated an angle of slope of 1 on 1 when actually it was 1 on 1.51. Consequently, about 20 000 more yards of material had to be removed than the contractor had calculated. Recovery for the extra work was denied. Emphasis was placed upon the fact that the contractor had agreed in the contract to perform "the entire removal and disposal of the masonry and rubbish of the reservoir" (57).

In a contract for the construction of a part of the Catskill Aqueduct a plan showed the types of tunnels to be constructed (58). Beneath the invert and resting on the bottom of the excavation, square and round drains were shown. These drains were to be installed so that "the bottom of the tunnel may be free from water and sufficiently dry at all times." Dimensions were given for all details on the plans except the drains, but their size could be determined by scaling. The contractor contended that a drain of this size could not carry off more than 70 to 80 gal per min. It was argued, therefore, that the drains shown on the plans implied a warranty that the water to be handled would not exceed that quantity. Finding it necessary to dispose of as much as 560 gal per min, the contractor sued to recover the extra cost of drainage and of excavating rock under these unusually wet conditions.

Recovery was denied. The Court stressed contract provisions which called attention to the uncertainty of the sub-surface to be encountered and which directed the contract or to provide all necessary pumps, pipes, and drains at his own expense (59).

An ingenious argument was advanced for the implication of a warranty in a case in New York City (60). The contractor was directed to remove "earth, rock or other material overlying the sub-grade" of a roadway. When rock was found, he objected that its removal was not required by the contract. He pointed out that, many years before, the City had let a contract for the removal of all rock "overlying the sub-grade," and that the work done under that contract had been accepted by the City. He claimed, therefore, that he was justified in assuming that the other contractor had removed all the rock, and that there would be none left for him. His suit to recover the cost of removing the rock was unsuccessful. The Court held "that the acceptance by the City of the prior work was not a representation of anything, upon which this contractor was entitled to rely" (61). Of interest in this connection is a case decided by the New York Court of Appeals in 1938, involving the construction of the New York State Building in the City of New York, wherein the superstructure contractor was held entitled to recover damages for the delay occasioned by the fact that the foundation plans had to be altered to meet unexpected subsoil conditions (62). The foundation plans, it was said, were a warranty to the superstructure contractor as to the anticipated time for the commencement of his work.

Engineers' Estimates.—Attempts to base claims for damages upon an engineer's inaccurate estimate of the quantity of work to be done have been generally unsuccessful. The usual contract clause stating that such estimates are "approximate only, * * * are given to form a basis of comparison for testing bids, * * * are not guaranteed to be accurate, and are not considered as a binding feature of the contract," is generally sufficient to negative the existence of the warranty.

In several cases (63) where recovery for work in excess of the quantities included in the engineers' estimate was denied, the rulings apparently were centered around the proposition that the estimates formed no part of the contract and were ineffective to limit the amount of work to be done thereunder. As a corollary to this proposition, it has frequently been held that no action can be maintained for loss of profits if the engineer has over-estimated the quantity of work to be done (64).

Implications in Specified Methods.—Closely related to the principle that an owner impliedly warrants the sufficiency of his plans and specifications to accomplish the intended result (65), was the situation presented in litigation over the construction of a sewer in Yonkers, N. Y. (66). The contractor argued that the contract contained an implied warranty that the sewer tunnel was to be constructed in "free air." The claim was based on the fact that the contract "set forth various features of the construction work required of the contractor which could be used only in a free air tunnel." Those "features" were: (1) The installation of under-drains; (2) the drilling of alignment holes; and (3) ventilation, concrete work, and care of water to be done by methods suitable only in a "free-air" job.

For 6 142 ft of 8 553 ft of tunnel, the contractor encountered a soft, water-bearing soil which required construction by compressed air. Suit was brought to recover the higher cost of doing the work in this manner.

The Court held that "the stipulation that these free air methods be used was a representation that the job was free air tunnel construction work," and that the contractor was entitled to recover. Of the contract provisions urged in defense (67), the Court stated that they could not be assumed to nullify the evidence in the plans that the contract was primarily for a free air tunnel (68); but the Court also observed that the contractor would not have been entitled to rely upon the representations if the borings, annexed to the contract, had indicated the presence of the water-soaked material. The attempt to advance this argument in defense failed because the testimony did not establish clearly what the borings really indicated.

In another case, the contractor argued that a warranty as to the character of the rock to be removed was to be inferred from the fact that the specifications provided for the use of light charges of explosives and for the completion of the entire job within six months (69); but the contention was unsuccessful. Recovery was denied. The Court held that no warranty could be implied, "particularly in view of the fact that there is no evidence indicating that by the use of more men and the employment of more equipment the task could not have been completed on time."

In litigation resulting from a contract for the construction of three giant piers in New York Harbor, the contractor argued, among other things, that a warranty as to the nature of the rock to be removed was to be inferred from the fact that vertical faces of the rock walls were to be produced by "channeling, or by drilling and broaching" (70). It was argued that a vertical face could not be produced by the methods specified unless the rock was firm and solid, and that, therefore, the contractor was justified in assuming that the rock would be of that type. The attempt to charge the City of New York for the extra expense of removing a large quantity of loose, rotten, shattered, and disintegrated rock failed. The evidence indicated that the specified methods would have been prescribed even for the kind of rock actually encountered. Therefore, the provision for "channeling or drilling and broaching" meant nothing at all with reference to character of the rock to be removed.

In another case, a contract provision that "tunneling will not be allowed without the approval of the engineer, and the method of tunneling shall be subject to his approval," was successfully used in defense of a claim for extra payment for the cost of removing an unexpectedly large quantity of rock (71). It was held that the contract clause should have warned the contractor that rock might be encountered and, accordingly, cast upon him the burden "of ascertaining for himself just the conditions to be encountered in the building of the drain or sewer."

Of course, if the contractor is left free to develop his own methods of accomplishing the result intended and is not circumscribed by specific contract requirements (72), the argument for the implication of this type of warranty cannot be made.

CONCLUSION

In the last analysis, each case, both past and future, must rest upon its own distinctive facts (73); but, in this matter, as in everything, a knowledge of what the Courts have done in similar circumstances lessens the element of uncertainty for the future. Even if it is too much to hope that risk can be eliminated entirely from sub-surface construction contracts, its existence and extent can be recognized in advance with the aid of earlier judicial decisions, to the end that costly mistakes for owner and contractor may be minimized.

(25) Elkan *vs.* Sebastian Bridge District, 291 Fed. 532 (1923). The Court said: "Of course any one would realize that the actual subsoil conditions

might, except where and to the depth shown by the borings, be different than so shown. The actual conditions were hidden. The borings were merely indications, at certain places and to certain depths, from which deductions might be drawn as to actual conditions along the line and to the depths of such borings. Both parties knew that deductions so drawn might prove untrue when the necessary excavations were made."

(26) The Court said: "The question here is who took the risk of these deductions? Either the district or the contractor must take this risk. Either could legally do so. Construction of the contract in the light of applicable legal principles must determine which did. That the district made known to Elkan the result of the borings is certain! This was done with one of two purposes: (1) To be the statement of a fact (subsoil conditions to be encountered) upon which he might rely and act; or (2) as useful information which he might accept as sufficient or not as he thought wise, leaving him to make such further and other investigations as he might wish." (291 Fed., at p. 538.)

(27) The Court said: "The bare statement that the boring sheet may be relied upon as accurate is entirely different from saying that the sub-soil along the bridge line is as shown by the boring sheet. One is a statement that certain evidence of an ultimate fact exists; the other is a statement that the ultimate fact exists. The statement here made goes, in effect, little further than if the boring sheet had, without comment, been furnished the bidder." (291 Fed., at p. 540.)

(28) The exact wording was as follows: "The excavation of this borrow-pit shall be carried to Elevation 655 D. and I. Datum, or to blue clay, which test borings show to be approximately fifteen (15′) feet below the surface. If the blue clay is above Elevation 655, none of the blue clay shall be excavated or placed in the embankment." (Detroit & I. Ry. Co. *vs.* Guthrie & Co., Inc., 72 Fed. (2d) 126 (C. C. A. 1934).)

(29) The Court wrote: "The only representation of fact made therein was that test borings had been made, and that they showed blue clay approximately 15 feet below the surface. The issue to be submitted to the jury was not whether there was blue clay nearer the surface than fifteen feet, but whether the representation that borings had been made and they showed no blue clay less than fifteen feet below the surface was true or untrue." (72 Fed. (2d), at p. 129.)

(30) The contract provided: "From borings and test pits, made at the site, it is assumed that rock will be found approximately as indicated on the drawings, but the United States does not guarantee the nature of materials to be encountered in the river bed, the correctness of the depth of rock as assumed or shown on the drawings, the depth to which it may be necessary to excavate, nor that the bottom of the river will not be changed before or after commencement of work." (Bates & Rogers Construction Co. *vs.* United States, 56 Ct. Cl. (U. S.) 49 (1921).)

(31) The Court said: "It would be extending the rule further than the adjudicated cases have gone, and further than we are prepared to go, to say that the Government can be held, as upon a warranty, of a condition as to which it makes no representation * * * when all it does is to furnish drawings which accurately state all they purport to show, notwithstanding it fails to state to the bidder that a hole was bored somewhere in or about the large area involved at some other time which disclosed that there was a log at the bottom of the Ohio River." (Bates & Rogers Construction Co. *vs.* United States, 56 Ct. Cl. (U. S.), at p. 60.)

(66) Montrose Contracting Co., Inc. *vs.* County of Westchester, 80 Fed. (2d) 841 (C. C. A. 1936).

(67) The principal clauses relied on read as follows: "That where material other than solid rock is encountered, containing loose sand or mud, which shifts with the water contained in it, and the Contractor chooses to use compressed air to pass through it, in order to partly relieve him of the additional cost of preventing and caring for the incoming water

and material or restraining it, an allowance will be made throughout the stretch where the compressed air is actually used under the above conditions of $30.00 per foot and for not more than six hundred (600) feet of length, where actually used, regardless of whether more be used or not."

"Maximum partial compensation for labor, plant and materials under compressed air when and if actually used as specified, but not in excess of 600 ft in length and Thirty and no/100 dollars ($30.00) per foot."

(68) The Court said that the contract provisions: "* * * cannot be given the effect of completely negating the representations in the plans that the tunnel was primarily a free air tunnel. They might have been effective to limit appellee's liability if the work had required somewhat more than 600 ft. of compressed air, but in point of fact, there was 6,142 ft. to be so built. These clauses cover a variation, not a transformation." (80 Fed. (2d), at p. 843.)

(73) Cauldwell-Wingate Company *vs.* State of New York, 277 N. Y. 365, at p. 377.

(74) The Circuit Judge said, in his decision favorable to the contractor: "I am led to believe that these prior investigations could have been obtained by the defendants and, in every sense of the word, should rightly have been in the possession of the complainants so they might be correctly guided in their proposal and estimates on the material to be handled. The suppression of all such prior information unquestionably worked a hardship, if not a fraud, on the complainant." (Citation Vol. 89, Federal Reporter 251.)

(75) The Court of Appeals reversed the lower Court, stating: "Trustees are not bound to exercise diligence to obtain information concerning the nature or cost of work for the benefit of bidders with whom they deal at arms length * * * and a contractor, for the excavation of a section of the drainage canal, is not entitled to a rescission of his contract because he encountered a substance more difficult and expensive to excavate than anything he was led to expect from an examination of profile and data in the office of the Chief Engineer."

Furthermore, there was "No provision in statute * * * which required that information concerning the nature of the materials to be excavated should be collected for the benefit of the bidders, and that such duty on the general principles of law or equity there is no foundation in authority or reason." (Citation 91, Federal Reporter No. 511, February 7, 1899.)

(76) The Court declared as follows: "On this appeal, defendants strenuously contend that the evidence shows that plaintiff drilled the greater portion of the time through shale and that the terms 'rock' and 'rock formations' do not include shale. To support this contention, defendants pro-

duced a petroleum engineer who testified that technically rock includes 'shale' or 'stone,' but in the oil field parlance the term refers to hard formations, usually in large bodies as, for instance, 'granite,' and further that 'shale' is not considered rock by oil people. The trial court interpreted the term used in the contract in its general sense and refused to interpret it in the limited fashion suggested by the expert. We agree with the interpretation of the trial court * * * the term 'shale' is defined as rock formed by the consolidation of clay, mud or silt, having a finely stratified or laminated structure * *, *. Under the circumstances, the general and popular meaning of the term is reasonably intended."

(80) 80 Fed. (2d) 841.

(81) 94 Fed. (2d) 580.

(82) The contract contained the following provisions concerning the use of compressed air:

"The Contractor hereby agrees to receive and accept as and for his full compensation for furnishing all the labor, plant and materials for, and building, constructing and fully completing and maintaining for 12 months all the work called for under this contract and for all the labor, plant and materials incidental thereto as required by the specifications and as shown on the plans of the work referred to therein, the following prices:

78-inch sewer in tunnel complete as indicated on the plans and specifications of this Contract, including shafts, portals, boat hole, manholes, alinement holes, sewer connections and all their appurtenances; except only any partial compensation for compressed air if used as listed in item 2 below; @ Nine hundred sixty-seven thousand and 00/100 dollars.

($967,000.00) lump sum Amount $967,000.00

Maximum partial compensation for labor, plant and materials under compressed air when and if actually used as specified but not in excess of 600 feet in length of tunnel @ Thirty and no/100 dollars.

($30.00) per foot Amount $18,000.00

Total sum bid in words Nine hundred Eighty-five thousand and 00/100 dollars.

Total Amount $985,000.00

"The above total includes all excavation, backfilling, waterproofing, masonry, concrete, reinforcement, forms, pipe, underdrain, fittings, sheeting, shoring, forepoling, timbering, piling, foundations, testing, maintenance, labor, plant, materials, insurance and all other things shown, specified or necessary for the full, watertight and enduring completion of the entire work.

* * * *

"That where material other than solid rock is encountered, containing loose sand or mud, which shifts with water contained in it, and the Contractor chooses to use compressed air to pass through it; in order to partly relieve him of the additional cost of preventing and caring for the incoming water and material or restraining it, an allowance will be made throughout the stretch where compressed air is actually used under the above conditions of $30.00 per foot and for not more than 600 feet of length, where actually used, regardless of whether more be used or not."

(83) 191 App. Div. 205, 181 N. Y. Supp. 137, aff'd 231 N. Y. 564, 132 N.E. 890.

DISCUSSION

Alonzo J. Hammond,[3] **Past-President, Am. Soc. C. E.** (by letter).—In 1934 a Committee of the Construction Division of the Society, on Substructure Engineering, presented a report which, subsequently, was published as Manual of Engineering Practice No. 8. The object of this work was:[4]

> "* * * to establish fair and equitable practice, and to correct undesirable procedures and abuses in the relations between owners, engineers, and contractors concerned with the design and construction of bridge foundations."

It is gratifying to note that the author credits the manual of practice with eliminating "much of the costly uncertainty involved in underground construction, with corresponding benefit to owner and contractor" (see "Synopsis").

He emphasizes the need of carefully worded specifications, but this does not carry with it the placing of all the burden on the contractor, as has been clearly stated. It is now considered best practice to give the engineer means and authority to obtain reasonably full and complete information of subsoil conditions, and to be responsible for such data.

In 1912, while conducting studies preliminary to the design of the Lake Street double-deck bascule bridge for the City of Chicago, Ill., the writer found information of borings made on each side of the river, about 250 ft apart, showing rock at Elevation −75.0 ft. That rock should be at such an exact uniformity of elevation raised a doubt in his mind as to whether it was bed-rock. New borings were ordered and confirmed the occurrence of rock at Elevation −75.0, but only 4 in. thick; so the driller continued down and found the bed-rock at Elevation −110.0.

The author has cited a number of border-line cases and the effect, on the Court, of the evidence presented by the engineer, as illustrated in the Fort Smith case (25). It seems reasonable to reach the conclusion that the engineer must set himself up primarily as an impartial judge, fair to both owner and contractor; otherwise a contestant does not reach conclusive knowledge of the law in the case until he reaches the Court of last resort, and it may not be on equity then.

To cite, briefly, a case in the Chicago district: The contractor was given certain information, but there were some additional borings referring to a material as "very hard," which borings were not shown. About 12 ft below the surface, the contractor found conglomerate rock, formed of boulders and clay cemented together, which had to be drilled and blasted and broken up before it could be shoveled. A favorable decision by the Circuit Court (74) in this case was later reversed by the Court of Appeals (75).

Engineers, generally, would consider the decision of the Circuit Judge in this case as representative of good law and common sense as against the decision of the Appellate Court.

---

[3] Cons. Engr., Chicago, Ill.

[4] "Engineering and Contracting Procedure for Foundations," *Manual No. 8*, Am. Soc. C. E., 1934, p. 3.

A contrary case of a decision of a lower Court being confirmed by a higher Court on a rule of reason is that of Schiltz *vs.* Akers, *et al.*[5] Action was brought by the plaintiff to recover the sum of $7 550, alleged to be due from defendants under the terms of a written contract for drilling of oil wells. The contract provided, among other things, "that in the event [and this is the important feature of the contract] rock is encountered in drilling any of said wells 'plaintiff agrees to drill one foot through the same without extra compensation, but beyond that defendants agree to pay $75.00 per day extra compensation for each day of nine hours required in drilling through all rock formations.'" The lower Court ruled in favor of the plaintiff, and the decision was confirmed by the Supreme Court (76).

As a young man the writer had a feeling of awe for the Supreme Court, until a very able lawyer tempered it by the remark that, although law in itself was an exact science, the interpretation by the Supreme Court was by some very human individuals. Contrary to the legal technicalities involved in some of the cases mentioned in the paper, the writer can cite the following as a common sense solution of a very difficult problem: On the main drainage canal from Chicago to Lockport, Ill., one firm of contractors had Sections 2, 3, and 4 at Lemont, Ill., the original contract calling for 27 cents and 28 cents per cu yd for glacial drift. The indurated clay was found to be almost as difficult to excavate as rock; and, therefore, by mutual consent, the contract was readvertised and the bids of four contractors ranged from 59 cents to 75 cents per cu yd for the same sections. The Chicago Sanitary District, however, finally made a new contract with the original contractor on the basis of 50 cents and 49 cents for Sections 2 and 4, respectively. There were, perhaps, two valid reasons for a renewal of the contract on the terms mentioned. The Trustees, no doubt, were willing for the contractors to recoup some of their losses, whereas the contractors, having their plant on the ground, were willing to make what appears as a low price compared to the bids of the other contractors.

The author has presented a most valuable list of case material for study by every engineer and contractor engaged in sub-surface work.

Frederick W. Newton,[6] **Assoc. M. Am. Soc. C. E.** (by letter).—An ideal toward which the engineer should strive in the preparation of a construction contract. The engineer is required to work with the tools at his disposal, however, and too frequently these do not include the complete investigation of sub-surface conditions which he would like to have. The complete investigation that should be made by an engineer before advertising a contract means more than simply making such borings and soundings as are necessary to determine the stability of the structure. It is recognized that in some cases such complete investigation is impossible.

The value in Mr. Herwitz's paper is that it helps to show how, in preparing a contract, the engineer may make the best use of such information as is available to him. The paper places too much emphasis on the wording of specifications, however (particularly the so-called "exonerating" clauses), and not enough on the facts. The statement in the "Synopsis" that "Experience in this type of litigation shows that emphasis is placed on carefully worded specifications, often with results expensively significant to one party or the other" is, to say the least, subject to question. Mr. Herwitz presents many instances where, in two or more cases involving contracts with the same or similar specifications, the result has been that in one the contractor was awarded increased compensation and in others the increase was denied.

---

[5] Supreme Court of California, Vol. 292, Pacific Reporter 463, October 20, 1930.

[6] Attorney and Counsellor at Law (Wait, Wilson & Newton), New York, N. Y.

The fact is that the Courts have endeavored to decide each case on its merits. In practice, a case is first decided and then an opinion is written explaining the decision. In most of the cases the exonerating clauses have been urged as a defense. Hence, these clauses are discussed in the opinions of the Court but, with the exception of a few cases in which there have been provisions of the contract or specifications relating to the particular matter in suit, it will be found that the facts, not the contract clauses, form the real basis of the decision.

The author recognizes this fact in his "Conclusion." He states that, in the last analysis, each case must rest upon its own distinctive facts. That being so, a discussion of this subject should direct attention to the facts that have led to litigation in the past, in order that a repetition of those facts may be avoided in the future. No exonerating clause can be drawn which will avoid the result of carelessness, negligence, or deception in the preparation of a contract.

Contract Should Describe Work Correctly.—The first and most important rule for the engineer who is preparing a contract is that the work to be done by the contractor must be described, clearly and accurately, in the contract. A bidder looks first at the "description of the work" and next at the bidding sheet. He makes a proposal for doing the work which the contract describes. If he is required to do more expensive work, he is usually entitled to increased compensation.

Where the contract described the work as "earth excavation," the contractor was entitled to additional compensation for excavating rock, Maney *vs.* Oklahoma City (2); a contract that called for the excavation of earth, hardpan, rock, etc., and defined each of these materials, did not include the excavation of adobe or gumbo where it was shown that these materials were not included in the definitions, Sweeney *vs.* Jackson County (3); a contractor who had undertaken to construct a tunnel in rock was entitled to additional compensation for a part of the tunnel that was in loose earth and water and required the use of compressed air, McGovern *vs.* City of New York (19); a contractor who had agreed to construct a tunnel in free air received increased compensation because he had to construct it in compressed air, Montrose Contracting Company, Inc. *vs.* County of Westchester (66); and, a contractor who had undertaken to construct a tunnel in solid rock with gunite lining received additional compensation because he was required to excavate the tunnel in loose rock and to place a monolithic concrete lining, City of Dallas *vs.* Shortall (34).

The cases in which the contractor has received additional compensation are not the only ones that show the importance of a clear and accurate description of the contract work. Other cases in which the owner has ultimately succeeded are equally persuasive because, if the engineer had been sufficiently careful in the preparation of the contract, the owner would have been saved the annoyance and expense of long litigation. In the case of Dean *vs.* Mayor of New York (4) the contract described the work as the grading of Dyckman Street from the Hudson River to Exterior Street. The drawings showed only a part of that work. It required litigation that went to the Court of Appeals to determine just what work the contractor was required to do. Dickinson *vs.* City of Poughkeepsie (3) is one of many cases that involve the question of whether a contractor for earth excavation is required to excavate hardpan. This difficulty may be overcome by taking bids for all excavation without classification, or by a sufficiently broad definition of "earth excavation," or by requiring that the contractor bid a separate unit price for hardpan excavation. In Barash *vs.* Board of Education (4) there would have been no lawsuit if the architect had been more careful to specify, fairly, the work that the contractor was required to do. The contract required the installation of Kalameined windows in all openings from a light shaft in an existing building. It was not clear whether this referred only to openings that the contractor was to make or to all openings, including those which already had windows.

Bidder Must Inspect Site.—The foregoing does not mean that a bidder may accept the description contained in the contract and "close his eyes" to facts that he knows or should know and which would demonstrate that the description is inaccurate. In Lentilhon *vs.* City of New York (4) the contractor undertook to remove the embankment forming the old reservoir at 42nd Street and Fifth Avenue, the site later occupied by the New York Public Library. He figured the contract on the basis of the slopes of the embankment shown on a plan which was not made from survey and not drawn to scale. He did not attempt to ascertain what the actual slope was although he might easily have done so. In Jahn Contracting Company *vs.* City of Seattle (34) a contractor for a sea-wall blindly relied upon a drawing made long before the grading of adjacent streets. A mere walking over the job would have shown that at the time of bidding the streets had been graded and that the line on the plan was wrong.

Representations Concerning Conditions Affecting Work.—After the contract provisions describing the work to be done by the contractor, the next subject is the information given to bidders concerning conditions that may affect the cost of the work. Such information may relate to subsoil conditions determined by soundings or borings, or to the sources of supply of materials, or to other conditions affecting the particular job.

It is recognized that, in general, the giving of information to bidders results in lower bids for the contract work because if bidders do not have the information, they are certain to make liberal allowances for contingencies. It is recognized, also, that engineers are subject to the temptation to make the contract appear attractive to bidders. In facing this situation the Courts have adopted certain rules which are undoubtedly fair and equitable. The difficulty arises in the application of these rules to the great variety of facts presented.

Borings.—It will probably be most helpful to discuss first the matter of borings. If borings have been made, bidders for the work should have the advantage of such information as those borings disclose. The question for the engineer is how this information should be given to bidders.

When engineers use borings, they draw lines from one boring to another and assume that between the borings the material will be substantially the same as that indicated by the borings. The Courts have recognized that this assumption is not always in accord with the fact. The Court ruled in Elkan *vs.* Sebastian Bridge District (25) that the giving of borings is not a warranty of the condition of the subsoil between the borings; and that all the owner warrants is that the borings have been correctly shown. In Groton Bridge and Manufacturing Company *vs.* Alabama and Vicksburg Railway Company (24) the contractor for the construction of bridge piers complained that the material encountered was unlike the material shown by borings which had been made near but outside the location of the piers. The borings had been plotted correctly, but there was a dip in the strata between the borings. The contractor did not recover.

In Detroit & I. Ry. Co. *vs.* A. Guthrie and Company, Inc. (28) the specifications stated that the borings showed blue clay in a borrow-pit 15 ft below the surface. The contractor found it much closer than that to the surface, but he failed to show that the borings were in error or that at the site of the borings the clay was less than 15 ft from the surface. The Court ruled that the fact that clay was found near the surface was some evidence that the borings were erroneous, but that, standing alone, such evidence was not sufficient.

The engineer may safely give to bidders all of the boring information in his possession, provided it is given accurately and without concealment. Among the cases cited by Mr. Herwitz in which this had been done and in which the contractors were not allowed to recover increased compensation are Foundation Company *vs.* State of New York (7); Pearson & Son Inc. *vs.* State of New York (8); and The Arthur A. Johnson Corporation *vs.* City of New York (10). A similar situation is presented in Murray *vs.* State of New York (8) but with the added fact that by reason of prior contracts in the same vicinity the contractor was entirely familiar with conditions and was not in any way misled by the borings. Irving Trust Company, as Trustee, *vs.* City of New York (21) presented an instance in which the boring information had been given to the bidder exactly as it was received from the boring contractor. The borings were inaccurate but the Court found that there was no proof that the city was aware of any condition different from what the borings showed, and disallowed the contractor's claim.

A clear illustration of the advantage of telling bidders just what preliminary investigation has been made is found in Kelly *vs.* City of New York (33) in which the contractor was denied a recovery notwithstanding the fact that the "probable surface of rock" shown on the drawings was incorrect. The contract described, correctly, the preliminary investigation that had been made, stating that some rod soundings had been made and the results were shown on the plan but were not warranted to be correct. This told the contractor exactly what had been done. The earth cover was not deep and he could have checked the soundings if he had cared to do so.

An engineer who furnishes borings or boring information to a bidder must exercise care that he furnish all of the information without distortion or concealment. If there has been distortion or concealment by which the contractor has been damaged, he is entitled to recover his damages. Cases of this kind are Christie *vs.* United States (13); United States *vs.* Atlantic Dredging Company (51); Jackson *vs.* State of New York (15); Stewart and Company, Inc. *vs.* State of New York (16). In the Christie case (13) the engineer who recorded the results of the borings had neglected to record logs and stumps encountered, which he considered of no importance. In the Jackson case (15) the State showed the results of one set of borings, but failed to show a set made some years earlier which indicated hard material. In the Atlantic Dredging Company case (51) the borings were given correctly but they did not penetrate to the full depth of the excavation required; and, although the engineer knew that the reason for not carrying the borings deeper was that they had encountered hard material, he nevertheless put in the contract the statement that the material was believed to be mainly mud, or mud with an admixture of fine sand. In the Stewart and Company case (16) the State gave information indicating soft material but withheld other information indicating hard material.

In these cases the giving of erroneous information or the withholding of information was not necessarily done intentionally or with fraudulent motive. In fact, in the Christie case (13) there was no question that the engineer honestly believed that the information concerning the logs and stumps was of no importance.

Statements Concerning Source of Supply of Materials.—The cases relating to the source of supply of materials for highway work show again that the decisions are based on the facts of each case rather than on exonerating clauses of the contract.

In Gross and Son *vs.* State of New York (49) the representation was made on the contract drawings that stone would be found in a ledge near a certain station. By a provision of the contract the contractor warranted that he had personally investigated the local sources of supply. He had made no such investigation and when he went to look for the stone after the contract was made he found a level field with no sign of stone. He wrote to the engineer that he had "assumed" that the information on the plan was correct. He had no right to make such assumption in the face of the provision which required that he personally investigate that particular matter.

In Atlanta Construction Company *vs.* State of New York (50) the contract contained a similar statement and the contractor recovered additional compensation because afterward it developed that the land on which the stone was located was in the possession of a life tenant who did not have the right to sell the stone. The difference between this case and the Gross case (49) is that in this case the bidder had done what the contract required; he had investigated and had found the stone. The Court found that there was a mutual mistake but one for which the State was responsible by reason of its direction and statement in the contract.

Semper *vs.* Duffy (23) and Brennan Construction Company *vs.* State of New York (49) are cases in which the State merely gave to bidders the reports of the probable location of materials, made by its field engineers to their superiors. The Court said that such reports were "suggestive merely, directing him (the contractor) for inquiries to what the State considered the nearest available source of supply."

An instance of a special provision that proved a bar to a recovery by a sub-contractor occurred in Kuhs *vs.* Flower City Tissue Mills Company (48). The contract provided that good gravel would be found in the excavation, but if sufficient gravel were not found, the sub-contractor should furnish gravel of equal quality. There was some gravel but not enough. In obtaining gravel from other sources the sub-contractor had done no more than he had agreed to do.

Other Cases Involving Representations.—Other cases in the group characterized by lawyers as "breach of warranty" cases show the necessity for both care and good faith in the making of statements or representations which may affect the cost of the work.

The leading case is Hollerbach *vs.* United States (45). The facts are stated in Mr. Herwitz's paper. The lesson for engineers is that no general exonerating clause will overcome the effect of a positive statement negligently or carelessly made in a contract. Another application of the rule is found in Delafield *vs.* Village of Westfield (46).

In the two foregoing cases the engineers did not know that their statements were wrong; but the statements had been made carelessly. Passaic Valley Sewerage Commissioners *vs.* Holbrook, Cabot and Rollins Corporation (17), the facts of which are stated by Mr. Herwitz, presents a situation in which the engineers did know that the borings did not disclose the true condition. They knew that the presence of the cemented formation was essential to the prosecution of the work; and, they knew that in the two prior attempts to build the tunnel this formation had not been found. Their attempt to shift the burden to the contractor received from the Courts the treatment which it deserved.

Representations as to Ground Surface Elevations.—There are two cases in which the facts are very similar; in one the contractor recovered; in the other the architect and Board of Education felt that the contractor should recover, but they were overruled by the Courts. The first of these cases is Pitt Construction Company *vs.* City of Alliance, Ohio (37) in which the Court held: That the contractor was entitled to use the ground-surface elevations given on a detailed plan for the work; that he was not required to make a survey to determine that those elevations were correct; and, when it was found that they were wrong, that he should have additional compensation. In the other case, T. J. W. Corporation *vs.* Board of Higher Education of the City of New York (52) there was a similar error in the elevation of ground surface given on the plans; but here the Court ruled that the contractor could not recover. The reason for the difference in the two decisions is that in the

Pitt Construction Company case the contract contained no reference about checking the elevations although it did contain the usual clause in regard to the contractor's inspection of the site. In the T. J. W. Corporation case there was an express provision in the contract which required the contractor to check the grades.

A similar result was reached in Conners *vs.* United States (35) where the contract showed approximate rock levels but contained a provision that the bidder must satisfy himself as to the accuracy of these levels and as to rock surfaces in general.

Equality of Opportunity.—Throughout many of the cases on this subject there runs the question of "equality of opportunity." If conditions are such that the bidder's opportunity to know them is as good as that of the owner, the Courts hold that the bidder should have taken advantage of that opportunity.

In Odell *vs.* City of New York (6) the contractor complained of an excess quantity of water encountered in the construction of a part of the New York City Aqueduct. The Court found that not only was there no representation of the quantity of water that would be encountered, but also that at the time of bidding, test pits along the line were open and the contractor had as much opportunity as the City to estimate the quantity of water. It did not appear that either party had made any attempt to measure the flow. In Faber *vs.* City of New York (22), on the other hand, the Court held the City responsible for an error in the elevation of rock, as shown by its borings, on the ground that the rock surface was far below the bottom of the river and that the contractor could not have been expected to make borings.

It should be noted, however, that a provision that the contractor must inspect the site does not require that he make borings or other investigations to determine that positive information given him in the contract is correct. For example, in the Hollerbach case (45) the court remarked that the contractor might have ascertained the true nature of the material back of the dam by the simple device of making rod soundings, but in view of the positive statement in the contract, he was not required to do so.

The rule seems to be that a contractor may rely upon the accuracy of the grades, including rock-surface elevations, given him in the contract; but if the contract expressly requires that he check such grades or elevations, and if the conditions are such that he might reasonably have done so before bidding but he has failed to do so, he should not complain if it is afterward found that the grades or elevations were in error. It is understood, of course, that this statement is not applicable in a case that involves deception. The author has called attention to the rule that no man may contract against his own fraud, City of Lima, Ohio *vs.* Farley (11), Bridger *vs.* Goldsmith (12).

Prior Work on Same Site.—The question sometimes arises as to the right of the contractor to rely upon information obtained from prior contracts. Dunn *vs.* City of New York (23) shows that a bidder, who looks at a prior contract and assumes without investigation that the work required by that contract has been fully performed, does so at his own risk. In that case a paving contractor assumed that the grading had been done under a prior contract. His own contract required that he do grading and he could easily have ascertained whether or not any grading was necessary. The Court held that the specifications of the prior contract, which were not made a part of his contract, did not constitute a representation on which he could rely.

In Cauldwell-Wingate Company *vs.* State of New York (35) the specifications for the prior contract were referred to in the claimant's contract. The contract was one to build the superstructure of the State Office Building in New York City. The prior contract was one to build the foundations. Because of unexpected sub-surface conditions, additional work requiring nearly a year for its performance was required of the foundation contractor, and this delay increased the cost of the superstructure. The contractor for the superstructure recovered, notwithstanding the contract provision that he should not be entitled to damages for any delay from any cause, including the act or neglect of the State.

Cases in Which There Was No Representation.—To establish a claim for increased compensation on account of an alleged breach of warranty the contractor must show that information has been given to him upon which he relied in making his bid and that such information was erroneous. He must show also that he had a right to rely on the information. The claims of the contractors in several of the cases cited by Mr. Herwitz failed because no representation had been made.

An example of this is Allen N. Spooner and Son Inc. *vs.* City of New York (21) in which the contractor complained that he had encountered loose rock in the construction of a pier. The City had shown two typical cross-sections, one for solid rock and one for loose rock, and had stated in the contract that no core borings had been made.

In another case, Maryland Casualty Company *vs.* Board of Water Commissioners (39), rock grades were shown on the plan but specifications required that the excavation be carried to the grade shown or to such increased depths as may be necessary to obtain a firm foundation. The contract contained a separate unit price for extra excavation below the grade shown, and this price had been paid to the contractor. The Court ruled that this negatived the idea of a representation that the rock would be at the grade shown, and that the contractor had received all of the compensation to which he was entitled.

In Simpson *vs.* United States (41) the work was done according to plans which the contractor had himself prepared without any information whatever from the United States as to sub-surface conditions. It was his responsibility, not that of the United States, that the design was not suited to the conditions which existed on the site.

Weston *vs.* State of New York (63) was a case in which the contractor claimed increased compensation because he was required to excavate more rock than was indicated in the engineer's estimate. He had been paid the rock-excavation price for all rock removed. The Court ruled that as there was no claim of deception, inequality, or inequity, the contractor was not entitled to increased compensation.

The Weston case (63) presents the question of the contractor's rights under a unit-price contract where there has been an increase in the quantity of one item. In the usual case such increase does not entitle the contractor to any payment beyond the unit price bid; but this rule is not applied if the increase is so great as to change, radically, the nature and cost of the contract as a whole.

Specifications Should Describe Finished Work, Not Methods of Construction.—The aforementioned cases have dealt with representations as to the work to be done or as to conditions affecting the work. There is another group of cases that should be helpful to engineers in the matter of drafting specifications. A contractor who has done the work according to the specifications is entitled to be paid the contract price although the result may not be what the owner anticipated. In three of the cases cited by Mr. Herwitz, MacKnight Flintic Stone Company *vs.* Mayor (65), Filbert *vs.* Philadelphia (65), and Kuhs *vs.* Flower City Tissue Mills Company (48), the owner sought to obtain watertight construction, and for this purpose gave to the contractors specifications which described in detail how the work should be done. In each case the contractor had done the work according to the specifications, and in each case the Court ruled that the contractor was entitled to be paid even if the structure leaked. In another case, Montrose Contracting Company, Inc., *vs.* County of Westchester (66), the owner had specified the methods to be used in the construction of a sewer tunnel. It was shown that those methods were appropriate for the construction of a tunnel in free air, but not for one in compressed air, and the Court held that the specification of those methods constituted a representation that the job was a free-air tunnel.

Mr. Herwitz has presented two cases which involved the same legal principle as the foregoing cases, but which relate to the plans rather than to the specifications. In United Construction Company *vs.* Town of Haverhill (38) the Court held that a contractor who had built bridge piers to solid ledge, at the depths indicated on the drawings, was entitled to be paid even if the piers were washed out in a subsequent storm. In United States *vs.* Spearin (65) the Court held that a contractor who had constructed a drain and had connected it with an existing drain, as required by the plans, was entitled to the damages suffered by reason of the fact that the existing drain was not sufficient to carry off the water which accumulated on the work during a storm.

The principle that underlies all of the cases in this group is that the owner is responsible for the sufficiency of the drawings and specifications. If, because of defects in the drawings or specifications, the completed work is defective, or the expense of doing the work has been increased, or the contractor has been induced to bid too low a price for the work, the responsibility is upon the owner, not upon the contractor.

Questions Arising During Performance of Work.—Mr. Herwitz has also cited a group of cases involving questions that have arisen during the performance of contract work. The questions presented do not relate to the assumption of risk of subsoil conditions, which is the subject of Mr. Herwitz's paper, but they are of such importance to engineers and contractors that it is fortunate that he has considered them.

The first of these questions relates to the engineer's final certificate. Nearly every construction contract contains provisions that the final certificate of the engineer is conclusive upon the parties and that such certificate must be made and filed before the contractor is entitled to receive his final payment. There is no doubt that if the certificate is made in good faith and in accordance with the terms of the contract, it is conclusive, and the contractor cannot recover as payment under the contract more than the sum certified, O'Brien *vs.* City of New York (5) and United Construction Company *vs.* St. Louis (32); but, if the Courts are convinced that an injustice has been done either because the engineer has been arbitrary in the making of his final certificate or because he has misconstrued the contract, they do not hesitate to set aside his certificate and to determine for themselves the sum due the contractor, White *vs.* United States (77), L. P. & J. A. Smith *vs.* United States (78), St. George Contracting Company *vs.* City of New York (79). The rule is firmly established that the final certificate is not a bar to an action for damages for breach of contract or breach of warranty in the making of a contract, Kuhs *vs.* Flower City Tissue Mills Company (48), Faber *vs.* City of New York (22), and Borough Constructor Company *vs.* City of New York (41).

Changes in Work.—Few large jobs are completed without changes in the drawings or specifications, additions to the work, or elimination of parts of the work. If the work is rendered more expensive, whether because of unforeseen conditions existing when the contract was let, as in Faber *vs.* City of New York (22), or because of any act or neglect of the owner after the making of the contract, as in Sundstrom *vs.* State of New York (9), Feeney and Sheehan Building Company *vs.* State of New York (9), Thileman *vs.* City of New York (55), the contractor is entitled to increased compensation. In such case no written order is necessary and the sum recovered by the contractor is technically recovered as damages, not as payment for extra work.

The elimination of work frequently results in hardship to the contractor because in making up his bid he has apportioned his indirect cost, overhead, and profit over the pay items of the contract. The elimination of work does not usually reduce the amount of the contractor's indirect cost and overhead, and it certainly deprives him of a part of his undistributed profit. Notwithstanding the hardship imposed, the Courts do enforce contract provisions permitting the elimination of work without liability for anticipated profits. Kinser Construction Company *vs.* State of New York (64), and in the case of New York City subway contracts, the Courts have enforced a provision that work may be eliminated without liability to the contractor for anticipated profits, overhead, or damages. In Del Balso Construction Corporation *vs.* City of New York (64) the Court said that the contractor must have had the contract provision permitting omissions in mind in calculating his overhead when preparing his bid. Even if the bidder does have it in mind, however, what can he do about it? He cannot foretell what items will be omitted, and certainly the City will not want bidders to add a contingent item to cover possible omissions of work. In view of this decision, the Board of Transportation, City of New York, should revise its omission clause, or, if it wishes to retain the unrestricted right to omit parts of the work, it should make provision for payment to contractors of the proportionate part of indirect cost and overhead applicable to the work omitted.

Conclusion.—A discussion of these cases would not be complete without a restatement of the rules to be observed by the engineer, and other rules that should be observed by the contractor. Among those rules the following stand out as most important:

For the engineer—

(1) The "Description of Work" in a proposed contract must describe, correctly, all of the work that the contractor will be required to do;

(2) All available sub-surface information should be given to bidders with complete information as to how, when, and by whom such information was obtained;

(3) A general statement concerning sub-surface conditions should not be made unless it is known that such statement is correct;

(4) An owner who has given the contractor inaccurate or incomplete boring information is responsible even if the boring information is not made part of the contract;

(5) A contractor is not required to make surveys, soundings, or borings to determine whether or not the information given him in the contract is correct;

(6) The Courts do not look with favor upon a one-sided contract, a contract that attempts to shift all of the risk to the contractor;

(7) If there is a subject as to which information is not complete and as to which it is intended that the contractor shall assume the risk, the contract should refer particularly to that question and the risk to be assumed should be clearly stated; and

(8) The specifications should tell a contractor what he is to do; they should not tell him how to do it.

For the contractor—

(9) The entire contract and specifications should be studied with particular reference to any provision directing attention to a special subject (it may be assumed that the engineer did not insert such provision unless the subject was one concerning which there was some uncertainty);

(10) A bidder should always inspect the site and is charged with knowledge of everything visible on such inspection;

(11) A bidder is not usually required to make borings or other sub-surface investigation, particularly if that work has been done by the owner; but the bidder is required to make any reasonable investigation which time and circumstances permit;

(12) Unless a prior contract for work on the site is referred to in the contract for which a bid is being made, the bidder is not justified in assuming that the work has been done according to the drawings and specifications of such prior contract; and,

(13) The owner is primarily responsible for the sufficiency of the drawings and specifications; but this will not protect the contractor if he knows, from facts presented to him or facts that were visible when he made the contract, that the drawings and specifications were not adequate.

David A. Molitor,[7] M. Am. Soc. C. E. (by letter).—Every sizable construction contract involves at least some features, the details of which are not predictable at the time of letting, and these must be appraised, when encountered, and allowed for in the final settlement.

Despite the most careful soil investigation and borings, made to obtain data for foundation design, there will usually develop, during construction, more or less material variations in the character and required depth of excavation, resulting in modifications from the design as originally prepared. To pass this risk on to the contractor, as is usually done, by introducing cleverly worded clauses into the specifications, is unwise and unbusinesslike, and generally leads to a case of arbitration or lawsuit.

If the designing engineer expects to deal honestly with the prospective contractor, he should write his specifications with that end in view. He should expect to pay for everything that is stipulated to be done or furnished without hoping to get something for nothing. Neither should the owner have to pay for anything not obtainable in fact.

Therefore, why not write a clearly worded specification covering everything, so far as knowable, in exact businesslike language, leaving the unforeseen eventualities to be dealt with under supplemental written agreements, and thus avoid serious disputes at the time of final settlement?

The wide variety of cases cited by the author illustrates the attitude of the Courts when called upon to clarify the business relations between owner and contractor, resulting from doubtful or contradictory requirements in the specifications with regard to the amount of work to be performed, usually under a lump-sum contract.

If the engineer cannot stipulate, clearly, the exact quantities of work which the contractor is to perform, and yet expects to hold the latter to a lump-sum price, he must also expect to obtain excessive bids covering the unreasonable, or inadequately described, features of the proposed work. Later, if the contractor finds himself a party to a losing contract, the case goes to Court for the final adjudication of disputes following in the wake of an ambiguous contract. As a matter of fact, lump-sum bids are generally unfair to both owners and contractors and should be avoided.

The practice of awarding contracts only to the lowest responsible bidder makes it mandatory to provide a method of obtaining comparable bids, but not necessarily lump-sum bids. This can best be accomplished by incorporating in the tender an approximate estimate of quantities of each kind of work or materials to be furnished, the bidder merely supplying the requisite unit prices to determine the aggregate amount of the proposal. The same unit prices should later apply to changes in the estimated quantities made necessary during prosecution of the work by additions to, or abatements from, the estimated quantities in arriving at the final estimate and settlement.

Extras, limited to work or materials not covered by the drawings and specifications, and hence not contemplated under the contract, are to be paid only in accordance with supplemental written agreements on a cost-plus basis.

---

[7] Cons. Engr., Harlingen, Tex. Mr. Molitor died September 8, 1939.

There will always be abundant evidence to cast doubt on the most carefully made soil investigation, and nothing further is necessary to start a controversy whenever the contractor sees his way clear to recover. One of the most fertile contentions for extra compensation is that not all the information was disclosed at the time of bidding.

The result obtained from the soil investigation should be accessible to all bidders merely for what it is worth, frankly recognizing the approximate, or even erroneous, character of the information, with a clear statement that all departures from the design data and changes in foundations as finally decided upon and built, shall be adjusted in the final estimate at the unit prices named in the bid.

If each intending bidder were to obtain his own information, this would necessitate duplicating the soil investigation, which is impractical. Any requirement whereby the bidder is to obtain technical data relative to depth and character of foundation, ground-water, pumping, sheet-piling, etc., and then be held responsible for the outcome, is manifestly unfair as it amounts to doing precisely what the designing engineer is supposed to do to obtain the required information for his own use and for all intending bidders. Contractors should not be penalized for shortcomings in the design. This is the responsibility of the engineer.

The very valuable advice contained in Manual No. 8 may be regarded as an enabling act to specification writing; but here again one finds a wide divergence in the quality of the product put out by different writers. It is sometimes easier to tell the other fellow how to do something than to do it oneself.

The author has presented innumerable cases which terminated in disputes in connection with "unexpected risks," and has cited the decisions rendered by the Courts on the basis of facts disclosed in each case. Although this information is very interesting and instructive, the matter of avoiding a recurrence of such cases is still an important issue. The writer contends that there is no justification for writing a contract based on a gamble.

F. B. Marsh,[8] M. Am. Soc. C. E. (by letter).—The conclusion that "a knowledge of what the Courts have done in similar circumstances lessens the element of uncertainty for the future" (see "Conclusion") is justified only for those types of cases in which the Courts agree among themselves. However, a reading of this paper confirms the previous feeling that in too many cases one Court decides in favor of the plaintiff and another Court, with a quite similar set of circumstances, decides the other way. One cannot escape the feeling that in one case the plaintiff's counsel or witnesses have appealed successfully to the Court's sympathy, or perhaps the weather or some other extraneous matter has given the Court a more generous disposition. Certainly the evidence alone does not account for many rulings, and precedents can be found for almost anything.

The one important fact that stands out is the obligation resting on the engineer to show the available sub-surface information not only accurately, but completely, including, for example, such data as the records of borings that had to be abandoned before the desired depth was reached. It may be that the reason for abandonment may, in itself, give a clue to sub-surface conditions not fully revealed by a subsequent deeper hole near-by. In any case, the listing of abandoned holes with the others is obvious evidence of the engineer's effort to make all information available.

---

[8] Div. Engr., Eastern Dept., New York Board of Water Supply, White Plains, N. Y.

Evan S. Martin,[9] Assoc. M. Am. Soc. C. E. (by letter).—The author views the problem and record from the legal standpoint. It has been common to insert, in construction contracts, general clauses that transfer the risks from the owner to the contractor. Acceptance of many of these risks may be optional with the owner, or he may pass them along; but certainly it is the duty of the owner to define the substance of the contract—to describe to the contractor what he is to do—if he invites a bid price.

The paper is predicated on the assumption that, in sub-surface construction, there are facts, essential to the completion of the contract, that have been overlooked in preparing plans and specifications. The writer maintains that a clause which places all risk of sub-surface conditions on the contractor renders the contract, basically, null and void. To cite an above-surface parallel: A contractor cannot be enjoined to construct a 12-room residence "of the best material and workmanship, to the satisfaction of the owner" without plans and specifications—that is, without knowledge of what is above the surface. The lawyers and Courts will not say so; they have not said so yet; but this continent has not emerged mentally and morally from wild free-shooting frontier conditions. When the people do emerge and really establish law and order, they shall be civilized because they will consider equity first and only. Whether the owner pays less for investigation than he does for contracting for something "in the dark" is irrelevant.

When the Construction Division was organized, in 1925, the writer stated that he thought that this section should consider the development of rules for the interpretation of contracts—an engineers' jurisprudence. There is no reason for engineers to defer to the legal profession in defining the ethics of their practice. Note the conflicting opinions cited in this paper; they are not much concerned with what is fair but, as a lawyer might say, what is fair "in the light of the contract." The writer's point is that the "light" is not in the contract but in equity behind the contract. What is fair is simple, in interpreting contracts; it is that neither party shall get something for nothing. In legal parlance "something for nothing" is "without consideration," and therefore null and void. It is not fair to force a contractor into the surety business; he is not organized to undertake risks, and he cannot know what to charge for them.

Engineers (and Courts, also) must delve behind the contract, "the law," and "the Constitution" to what is fair. Stated inversely, engineers must make ethics—equity—the sole guide in the interpretation and adjudication of contracts. Perhaps this is what is intended by Blackstone's British Common Law.

C. Maxwell Stanley,[10] Assoc. M. Am. Soc. C. E. (by letter).—The outline of the legal aspects of the risks involved in sub-surface construction, as presented by Mr. Herwitz, should be of help to every engineer who prepares specifications for such work. Although most engineers may have avoided litigation arising from unexpected conditions under the surface of the ground, few have avoided controversy with contractors, which has stopped short of litigation only because of compromise, extra compensation, or because the sum involved was too small to justify legal action.

---

[9] Secy.-Treas., Jas. A. Wickett, Ltd., Toronto, Ont., Canada.

[10] Cons. Engr. (Stanley Eng. Co.), Muscatine, Iowa.

As emphasized by Mr. Herwitz, there must be a complete "meeting of minds" between the parties to the contract if confusion and misunderstanding are to be avoided. Such a "meeting of minds" requires a full understanding, on the part of both parties to the contract, of the risks and the responsibilities to be assumed by each. Such an understanding can be obtained only through the contract documents, and, more particularly, through the specifications and the plans prepared by the engineer. Many of the cases cited by Mr. Herwitz obviously involve specifications in which the provisions regarding the risks and responsibilities have been vague or indefinite, thus preventing a "meeting of minds." In such cases, it is natural that disputes will arise which create controversy, and which may lead to litigation.

Every engineer should recognize that there are hazards involved in subsurface construction because experience has shown that no matter how carefully subsoil investigations are made, conditions may be encountered that are different from those anticipated. Likewise, every experienced engineer should realize that various types of subsoil require different methods of construction and types of equipment and, hence, result in different costs of construction. Furthermore, he should realize that if a contractor is required to assume the risk of unexpected subsoil conditions, that contractor is entitled to compensation for this risk and must include in his bid a sum sufficient to cover the item.

In preparing his specifications, the engineer has the three following choices of placing the responsibility for unexpected subsoil conditions:

(1) The entire responsibility may be placed on the contractor who must thus assume all risks and who will, of necessity, protect himself by including in his bid a sum which he estimates is equal to the risk that he must carry, plus the cost of any borings or investigations which he may make.

(2) The responsibility may be assumed by the owner by giving information on subsoil conditions and by guaranteeing this information. In this case, the risk is entirely upon the owner and the contractor need not protect himself by covering these items in his bid and, hence, may bid lower.

(3) The responsibility may be divided between the contractor and the owner. In such cases, the owner may provide available data on subsoil conditions but require the contractor to interpret them and be responsible for any misinterpretations or for any conditions which prove to be different from those indicated. Such a case saves the contractor the expense of borings but still makes him assume a risk for which he is entitled to proper compensation.

There are numerous circumstances which fully justify either of the first two choices, and there are undoubtedly some cases where the third choice is proper. It would seem, however, that the greatest difficulty has arisen in those cases in which the engineer has endeavored to "straddle the fence" and divide the responsibility between owner and contractor and has failed to state in the specifications, clearly and definitely, just what is intended. Sometimes the engineer has realized the shortcomings of the data he has available on subsoil conditions and, although he has used these to outline the general methods of construction and type of work on the project, he has endeavored to avoid the assumption of responsibility on the part of the owner by placing it upon the contractor through means of general or "catch-all" phrases in the specifications.

After the decision has been made as to who shall bear the responsibility for any unforeseen conditions, the specifications must then be prepared in such a manner that there will be a complete "meeting of minds." Vague and indefinite provisions and so-called "catch-all" phrases which are inserted in an effort to throw responsibility on the contractor while, at the same time, the engineer is endeavoring to specify methods and equipment, have no place in a specification. The engineer should state, fully, clearly, and fearlessly, who is to be responsible for unforeseen ground or subsoil conditions. If the owner is bearing the risk, the contractor should be instructed to bid upon the subsoil conditions as outlined in the data included in the specifications, and he should be compensated for unforeseen conditions which may change the cost of construction. Often, this can be taken care of by the use of unit prices on different types of material that may be encountered. On the other hand, if the contractor is to bear the responsibility, he should be made aware of it so that he may protect himself to whatever extent he deems necessary when he bids upon the work; and then, if unforeseen conditions are encountered, the specifications will be sufficiently clear and precise so that he has no valid claim for any additional compensation.

In all events, however, the specifications must be clear and precise and must deal fairly with both parties; and, they must bring about a complete "meeting of minds."

Francis J. Morgan,[11] **Esq., and Frederick C. Zeigler,**[12] **M. Am. Soc. C. E.** (by letter).—In the presentation of his paper, Mr. Herwitz has made a valuable contribution to engineers and others engaged in the preparation of construction contracts and their appurtenant specifications, plans, and documents where underground work is involved.

Sub-surface exploration work, in some cases (such as for tunnels and pipe lines) may be done primarily for the information of the engineer to guide him in establishing the location, grade, type, and shape of his structure. The character of materials and conditions encountered in borings may require radical changes in the engineer's preliminary designs so as to make these borings quite incomplete, if not unreliable, when used by contractors for bidding purposes. Sometimes complete deep borings are difficult to make especially in glacial drift where boulders abound and blasting is restricted in public thoroughfares. Drilling progress under such a condition is likely to be very slow with consequent long delay in letting the construction contract.

---

[11] Deputy, County Attorney, Westchester County, Yonkers, N. Y.

[12] Formerly Project Engr., Westchester County Sanitary Sewer Commission; and Project Engr., Bureau of Sewage Disposal, Dept. of Public Works, New York, N. Y.

Generally, the engineer on public work tries to obtain the best possible sub-surface data. If he employs a reliable and experienced boring contractor, it is obvious that the bidding contractors on the subsequent construction work have available as much information as to the nature of the sub-surface conditions as he has. Of course, the engineer is on "dangerous ground" when he attempts to interpret sub-surface conditions and draws on his own imagination as to the kind, form, and types of constructions or configurations of strata which the eye cannot see.

It should be the function of the engineer to protect, with great care, the interests of the owner or municipality for which construction work is to be done so that damage claims will be avoided or, if taken to Court, will not result in costly judgments. Waivers alone appear in certain cases to carry little weight in Court.

Since much of the public bidding on construction jobs is clearly a gamble on the part of many contractors, it behooves the engineer to use extreme care to make the provisions of his contract documents as tight as possible to protect the owner, especially if borings and other records are made available to bidders. It is unfortunate, but it must be admitted, that there are a few contractors who are quite ready to use, against the engineer, any honestly prepared informatory data that have been supplied to him in advance of bidding, especially where the contractor has been the loser financially through his own mismanagement or otherwise. The engineer must be prepared for that kind of a contractor.

It should be realized that on public work, the contractor usually can secure a Court order to make a "fishing expedition" to examine all the engineer's records for evidence to use against him in the Trial Court.

It is realized that it would have taken much space if the author of the paper had covered, in reasonable detail, the various Court Citations mentioned in the Appendix. Some of them, however, would probably be of considerable value to the engineer who is charged with the preparation of important contracts because the average engineer has little or no true conception of the judicial viewpoint.

In a 10-yr construction program in Westchester County, New York, the case of Montrose Contracting Company, Incorporated *vs.* County of Westchester (66) was the only one of several claims taken to Court by contractors, which finally resulted in a judgment in the contractor's favor. Bidders generally recognized that the work, a tunnel, was "a wet job," in a valley at considerable depth below the bed of a near-by stream. Sufficient information was available in the contract documents and borings to put the bidders on notice that the work was without doubt very wet. It is difficult, at least for a layman, to understand how a Court could be convinced that the contract documents, which clearly delineated wet conditions and required an examination of the site by bidders, meant anything else to experienced contractors than the necessity of using accepted methods under such circumstances to keep the work dry during construction.

In the first trial, the contractor contended that the contract provisions for under-drains, alignment holes, ventilation, care of water and placing of concrete tunnel lining in not less than 12-ft sections all indicated a free air job with the exception of about 600 ft of tunnel and that they could not be performed where compressed air was used. No defense was offered and the judge granted the County's motion for a directed verdict in its favor (80). The Circuit Court of Appeals on an appeal by the contractor reversed the judgment entered in favor of the County and ordered the second trial holding that as a matter of law the under-drains could not be built in compressed air; that the alignment holes required were used in free air but never in compressed air; that the specifications relating to ventilation, concreting and care of water were suitable for a "free-air" job and impossible of use in a compressed-air job.

Regardless of the fact that the County in the second trial offered expert evidence to show that the aforementioned provisions could be used in compressed air as well as in free-air tunneling the opinion of the Circuit Court prevailed and the contractor was successful in recovering a substantial judgment. The County then took an appeal to the Circuit Court of Appeals but was unsuccessful (81). The Supreme Court of the United States refused to grant Writs of Certiorari on both applications therefor made by the County, after each appeal had been decided by the Circuit Court of Appeals.

The lawsuit referred to herein presents a very interesting problem both for lawyers and engineers in that it relates to the interpretation of a contract, where mixed questions of law and fact are involved.

It is the duty of the Courts to interpret contracts and explain their meaning. The Trial Court on the first trial held in substance that the contract did not represent and impliedly warrant the tunnel job to be substantially a "free-air" job. That judge apparently interpreted the contract as it was written and especially those parts that referred to the use of compressed air. The words which related to compressed air, and the partial payment for 600 ft, specifically said "regardless of whether more be used or not" (82).

In its opinion on the first appeal the Circuit Court concluded that the compressed air provisions of the contract could not negate the representations in the plans that the tunnel was primarily one to be constructed in free air. It held further that the compressed air provisions covered a variation, but not a transformation, and that they would be effective if somewhat more than 600 ft of work were required in compressed air. It did not say how much more.

Furthermore, the Circuit Court took the evidence offered by the contractor and, with no evidence offered by the County, interpreted the contract to mean that the provisions of the contract relating to under-drains, alignment holes, ventilation, pouring of concrete in not less than 12-ft sections and the care of water applied to free air, and were impossible of use in compressed air.

If it is assumed that the trial judge on the first trial erred on the law in interpreting the contract, then questions of fact arose as to whether or not the aforementioned provisions of the contract applied both to free air and compressed air, and whether or not these things could be done only in free air and could not be done in compressed air.

As the case was tried before a jury, it seems that these questions, after the evidence thereon had been offered by both sides in the second trial, should have been given to the jury to determine as questions of fact. If this had been done and the jury had determined that these provisions of the contract could be performed only in free air, then the Court would have been in the position to apply these facts to the contract and hold that the contract represented, and impliedly warranted, the tunnel to have been substantially a "free-air" job.

Viewing it from the other side and assuming that the jury found these provisions of the contract could be performed in compressed air as well as in free air, the Court would have to say that there was no representation and implied warranty that the work was substantially a "free-air" job.

In his first opinion, did the Circuit Court judge stray from the beaten paths of the law and wander into the realms and fields of engineering and thereby become an engineer as well as a judge? Who determined the fact that the under-drains or the alignment holes could not be built in compressed air, or the ventilation provisions could not be used in compressed air, or that the care of water provisions was impossible of use in compressed air, or that concrete in at least 12-ft sections could not be poured in compressed air? It is a fundamental principle of law that the duty of a common-law jury is to determine and decide questions of fact. Furthermore, another question suggests itself and that is: Did the contract contain an "express warranty" that fixed the sum of money the County would pay specifically and directly for compressed-air work, and thereby require the contractor to include in Item 1 of the bid (this was a lump sum contract) any additional sum it needed to compensate itself for all compressed-air work costing more than $30 a foot, no matter how much was done under compressed air?

Different technicalities seem to arise in every Court case, which affects its outcome. Even the viewpoints of the Courts appear to differ; the Westchester case in point has no parallel. Care was taken to avoid specifying both the methods of construction and the results to be attained but the Court may have thought otherwise. A distinction has been drawn between constructional features which serve a useful purpose in the completed structure and those useful only during construction whether the engineer requires them for his use or not; such as, for instance, the alignment holes for checking tunnel lines from the ground surface.

Because of sub-surface conditions which a bidder seems to have disregarded this discussion shows what can happen in litigation regardless of the care in the preparation of borings and a seemingly fair and reasonable contract. It supports the author's conclusion that each case must rest upon its own distinctive facts. It appears, however, that the safest contract documents are those whose provisions are very general so far as possible; otherwise every conceivable contingency must be covered.

LAZARUS WHITE,[13] M. AM. SOC. C. E. (by letter).—The paper by Mr. Herwitz is very timely, of great value to the engineer, and is deserving of a full discussion. In the writer's experience very little on this subject is taught in engineering schools; yet contracts and specifications are primarily created by the engineer through his investigations, designs, and specifications, although the contract part of the documents may be the work of lawyers—and here "comes the rub." The engineer responsible for a sub-surface contract is often too hampered by a lack of time or funds to investigate sub-surface conditions properly; he then draws up designs, as nearly as possible fitting the conditions as known or assumed by him. He feels that if conditions are not actually encountered as assumed, claims for extra compensation will be filed by the contractor; and he relies upon the lawyer to protect the owner from such claims —hence, the "exonerating clauses" or "alibi clauses" found in many contracts. Thus, to the business risks and labor risks, which a contractor must assume, are added risks which do not properly belong to him. The owner should provide sufficient time and means for the engineer to ascertain the underground conditions properly; or, if this is impracticable, the owner should assume the extra cost of performing the work under conditions different from those upon which the contract was based. The engineer degrades his profession by hiding behind tricky legal defenses so that extra expenses (which, in fairness, the owner should assume) are thrown upon the contractor whose bid prices are usually narrowly competitive.

---

[13] Pres., Spencer, White & Prentis, Inc., New York, N. Y.

The engineer is properly the agent of the owner, and it is perfectly proper that as the owner should profit by the skill and economies of design of the engineer he should also assume the extra costs when the designs do not fit the assumed conditions, and when the conditions are different.

The "Synopsis" states that in the early days it was customary for the contract to provide that the risk of the unexpected should fall on the contractor. Broadly worded contract clauses took the place of scientific and careful investigation. Unfortunately this practice has persisted so that it is still common in contracts originating in certain organizations, as for instance, in the following note, attached to the principal sheet of an important contract.

"This record of borings is issued for the convenience of contractors. It is not a contract document. No figures nor notes are guaranteed. Sections and profiles are interpolated and are not exact."

Although Mr. Herwitz cites practically all the cases bearing upon sub-surface contracts and clearly defines the meaning of the decisions, there is no clear thread running through these cases and as he states in the last analysis "each case must rest upon its own distinctive facts."

The writer, from personal knowledge of several of the cases cited and with forty years experience in such sub-surface contracts, has sought to find some common logic in the series of apparently contradictory decisions, and has come to this conclusion that: (1) When the explorations, engineering and design, and the contract and specifications have been well done, the owner seldom loses; and (2) good and thorough engineering is the best protection and in most cases discourages litigation. Such contracts are consistent with the old definition of a contract being a "meeting of the minds." In other words a proper contract is that in which both parties agree upon a set of conditions upon which a price is based. Such contracts are not so uncommon; specifications of the U. S. Engineer Department contain clauses enabling adjustments and extra compensation to be made when "changed conditions" are encountered, or when designs must be altered because of "changed conditions."

Mr. Herwitz states that "reports of borings and similar data may return to plague both owner and contractor, even when given in the utmost good faith and with careful attention to the best modern practice." This seems to be apparent from the cases cited but again, in the writer's experience, the cases lost by the owners were not supported by well-prepared or well-explored contracts. The main difficulty with underground investigations is not that they are improperly made as much as improperly interpreted and classified—classifications made by a foreman rather than by a trained geologist. The Catskill Aqueduct crossed many buried gorges and difficult terrain; yet it was so well explored, and its geology so well investigated that little of the unexpected was encountered, and the few suits started were lost in the Courts. Of course the writer does not maintain that there is no residue of uncertainty in sub-surface work; but he believes that an arbitration clause is desirable to adjust claims arising from such uncertainties. A board of experts can come quickly to a just decision as compared to an ordinary jury. Almost manifest injustices will be avoided, as where public construction organizations use the sovereign power of the State to bar just claims or where clever lawyers write in trick clauses which serve as traps for the unwary.

In conclusion the writer would emphasize that the engineer prepare his contract thoroughly, act as a just judge in interpreting it, and forget that his judgment is "final and conclusive."

T. Kennard Thomson,[14] M. Am. Soc. C. E. (by letter).—Mr. Herwitz's very interesting paper draws attention to many cases in which Courts give diametrically different judgments on what, to the laymen, would appear to be identical cases. Most engineers have all had similar experiences.

The English Law Courts have the reputation (former Chief Justice Lord Reading has so stated within the writer's hearing) of trying to settle law suits on the equity of the case, instead of on technical legalities, as is so often done in the United States.

All that engineers can do is to try to be just to both client and contractor. In fifty-six years of experience the writer can recall only three or four cases in which the engineer deliberately tried to cheat the contractor. Few, if any, other bodies of men can equal or surpass such a record.

An engineer should give the bidders as much information as possible, and should explain, fully, the limitation of such information. It is neither wise nor pleasant to accept a bid when the "successful" bidder does not have a reasonable chance of making an honest profit. If the engineer furnishes the results of test "wash borings" he should explain that such borings give no indication of what kind of material lies under the bottom of such test borings.

In many cases the record states that the boring stopped on "rock or boulder." In some cases, such as Lower Manhattan, if the "wash boring" was made by an experienced engineer, he could tell which it was because he could wash up samples of New York bed-rock but could make no impression on a New York boulder.

---

[14] Cons. Engr., New York, N. Y.

With a sample smaller than a cherry he could state whether or not it was New York rock; but, a "core" or diamond-drill boring, penetrating from 3 ft to 5 ft into the rock, would be necessary for him to ascertain whether or not it was bed-rock in its original position, and not a misplaced or deposited piece of rock.

It is frequently difficult to interpret, correctly, the results of borings made by others. The writer once asked a contractor (who had, at that time, probably made more borings in New York than any other man) how much quicksand and hardpan he had found on a certain lot. The contractor replied, "none of either" and then showed the samples which confirmed what the writer already knew—that there was nothing but quicksand and hardpan above the rock at that place.

In some parts of Manhattan, an experienced man would know that he could reach hardpan with "wash borings" and find a fairly uniform level. At the same site the surface of the rock, even a foot or two away, might be entirely different. The writer recalls one case in which there was a drop of 6 ft in a horizontal distance of 2 ft. In such places the expense of many diamond-drill or "core" borings would scarcely be justified. At other points on Manhattan "wash borings" would be worthless, and nothing but "core borings" or test pits should be used.

The writer's practice for caisson work, where he is satisfied with the test borings, etc., is to call for a lump-sum bid to a certain depth, and for a price per cubic yard for work done below that depth. On one job he spent hours convincing the other members of the Board that they should make the estimated cost on the basis of $25 per cu yd to a stated depth and $50 per cu yd for all work done below that depth.

At first they could not see why so abrupt an increase should be made until it was explained that $25 was the average cost from zero to the stated depth, including plant, etc., and that $50 was a fair price for the greater depth. The irony was that, after convincing the Board and calling for bids on that basis, one contractor took a chance that he would not have to go below that level, and bid a flat $25 per cu yd. As an experienced contractor, he should have known better because the information was based upon "wash borings" only, which cannot be depended upon, with very rare exceptions, to reach bed-rock.

The call for bids asked for a price, per cubic yard, for 6 000 cu yd, more or less, below the stated depth. If he had bid $50 per cu yd for that item he would have received the contract anyway. The contractor lost money on that job, and would have lost much more if the Board had compelled him to go deeper as it had the right to do. It happened that the Board did not think it necessary in the interest of safety.

Experienced engineers have occasionally succeeded in carrying "wash borings" to bed-rock, through boulders and other hard material, by using dynamite or powder.

As an example of an unfair specification, a contractor once bid on some excavation work to be done by steam shovel at, say, 20 cents per cu yd. In that case the engineer had the privilege of changing the slope of the excavation if he considered it necessary, even after the excavation had been completed.

This meant that the contractor had to flatten the slope by pick and shovel at many times the contract price, and sometimes more than once at the same site. Although the engineer knew this was a rank injustice to the contractor (it was on public work), the engineer had no authority to pay more than the contract price.

Needless to say, books could be filled with descriptions of similar cases.

CARROLL A. FARWELL,[15] M. AM. SOC. C. E. (by letter).—A subject that has needed more study is presented in this paper, and its treatment by the author is of much value. The writer wishes to add emphasis to the importance of securing, in so far as possible, a definite "meeting of the minds" of the contracting parties. Each party must comprehend that there are risks to be taken and that the contract documents should allocate these risks clearly.

It appears that, in general, the Courts uphold the legality of placing a risk upon the contractor provided that the contract documents so state. Certain risks, which may not be mentioned specifically in the contract, are customarily assumed by the owner—such as, for example, extremely abnormal weather conditions or river floods, or hurricanes (in New England). Similarly, variations in the cost of materials and labor are customarily borne by the contractor. It would be better if the allocation of these risks were definitely specified instead of being left in the classification of "common practice." The risk of fire may be carried by either party and the allocation of this risk is often clearly defined in the contract through a specification that the contractor, or the owner, carry fire insurance. The risk involved in sub-surface conditions, to which the author's paper is limited, is one of the major items of construction work and, as such, needs accurate allocation.

Manual No. 8 states (1(*b*))

> "* * * The owner should provide the necessary funds for a complete preliminary investigation of the soil, its geological formation, and water conditions; and for the determination of all other facts needed to enable the engineer to design the work properly and the contractor to determine its cost accurately * * *. It is the contractor's duty to estimate only on work for which adequate preliminary information has been obtained, and for which adequate designs and specifications have been prepared by the engineer. He should not bid on the work until he has assured himself as to the adequacy of the information given him and the practicability of the type of construction shown in the engineer's design * * *.

The words "accurately," "adequacy," etc., are relative and their interpretation involves the personal equation. Regardless of how accurate and how adequate is the information given, there is a possibility of unforeseen conditions affecting the cost of the work, and the contract documents should specify which party is to bear, or is to be benefited by, the change in cost. Moreover, in order that the engineer may determine what are unforeseen conditions, the foreseen conditions must be shown or indicated definitely.

As has been stated, the contracting business is highly competitive and the writer agrees that the more the risks are carried by the owner, the lower will be the contract prices bid, and the more stable the contracting business. On the other hand, it is sometimes true that the owner is also engaged in a highly competitive undertaking, as for example, in the construction of an office building in which the cost of the building affects the rents that must be obtained; and, if the cost is greater than a certain limit, the project is not financially feasible.

---

[15] Cons. Engr. (Fay, Spofford and Thorndike), Boston, Mass.

Therefore, the owner may consider it desirable to carry as little risk as possible himself and to employ the contractor to carry all possible risks in order that he may know his upset cost as accurately as possible. This will usually cause the work of the contract to cost more than would otherwise be the case; but the additional cost may be well worth while. Moreover, the risk must be assumed by some one, even if it does not appear in the cost figures. If it were possible to arrange for some kind of insurance to cover such a risk (as is done by insurance against fire), the owner would undoubtedly be willing to pay for it, either directly or through the contractor.

If it were possible to include an item in the contract entitled "Assumption of Risk of Unexpected Sub-Surface Conditions," it would be highly desirable as it would call attention to the actual cost of carrying such a risk.

Public bodies, as well as private owners, often desire to know the upset cost of a project as nearly as possible in order to assure themselves that the cost will not exceed the funds available; and here again the contractor may properly be paid for the risk which he assumes.

The owner expects the engineer's estimate of cost to be reasonably accurate, and the Engineer should state (if it is a fact) that there are certain risks which may increase that cost over the estimated contract cost. This is often done under an item called "Contingencies" but many times this item is removed from the estimate when the contract documents are executed.

Under certain conditions, it has been the custom in the writer's office to arrange construction contracts for bridge foundations so that the contractor will be paid a lump-sum price for the foundations as built in accordance with the contract plans, and be paid under another item a unit price per vertical foot for the additional depth to which any pier may be carried below the depth indicated on the contract plans. This has been done on the theory that a decrease in depth was unlikely and, moreover, would have little effect upon the total contract cost, whereas each foot of additional depth would increase the cost materially.

As an example of an apparent lack of clarity in the "meeting of the minds" in a contract for foundations, the following, which came under the close observation of the writer, may be of interest.

The Contract Documents included the following:

> "ART. 3. *Changes.*—The contracting officer may at any time, by a written order, and without notice to the sureties, make changes in the drawings and (or) specifications of this contract and within the general scope thereof. If such changes cause an increase or decrease in the amount due under this contract, or in the time required for its performance, an equitable adjustment shall be made and the contract shall be modified in writing accordingly * * *.
>
> "ART. 4. *Changed conditions.*—Should the contractor encounter, or the Government discover during the progress of the work, sub-surface

> and (or) latent conditions at the site materially differing from those shown on the drawings or indicated in the specifications, the attention of the contracting officer shall be called immediately to such conditions before they are disturbed. The contracting officer shall thereupon promptly investigate the conditions, and if he finds that they materially differ from those shown on the drawings or indicated in the specifications, he shall at once, with the written approval of the head of the department or his representative, make such changes in the drawings and (or) specifications as he may find necessary, and any increase or decrease of cost and (or) difference in time resulting from such changes shall be adjusted as provided in article 3 of this contract."

The specifications included the following:

> "*Borings.*—Wash borings have been made under the direction of the contracting officer and of the engineer at various points at the sites of the work. These borings were made in the usual manner and with reasonable care; and their locations, depths, and the character of the material apparently encountered have been recorded in good faith on the contract plans. Samples of material obtained from the borings have been preserved and labeled and may be examined at * * * . There is no expressed or implied agreement that the depths or the character of the material have been correctly indicated and bidders should take into account the possibility that conditions affecting the cost or quantities of work to be done may differ from those indicated.
>
> "*Boulders.*—The borings apparently indicate that boulders may be encountered in varying numbers and sizes at any or all of the excavations to be made for the work."

During, and at the completion (1934) of, the work the contractor claimed, in effect: That the number of boulders and the quality of the sand encountered in the excavation was materially different from that shown in the drawings and indicated in the specifications; that, therefore, unforeseen and unanticipated sub-surface and latent conditions were actually encountered and it was necessary to change the method of work; and, that adjustments of the contract sum and of the contract time should be made to compensate for the extra work and time resulting from such changes. The controversy was finally taken to the Court of Claims and, in so far as is known to the writer, decision is still (1939) pending.

Oren Clive Herwitz,[16] Esq. (by letter).—Mr. Newton's discussion of the cases cited and analyzed in the paper was very helpful, for he refers in several instances to additional facts which the writer, because of space limitations, found it necessary to omit; but, with several of Mr. Newton's observations the writer is constrained to disagree.

Thus, Mr. Newton's statement that "an owner who has given the contractor inaccurate or incomplete boring information is responsible even if the boring information is not made part of the contract" is misleading and incorrect, for the Court of Appeals of the State of New York has held that in such a situation the owner is responsible only if guilty of bad faith. The Court said (42):

"If, however, notwithstanding the agreement as to honest mistake, damages might be recovered from the State for misrepresentations, upon which the bidder might rely, the boring sheet was not such a representation. It formed no part of the plans upon which the contract was based. It was not prepared or used for that purpose. It was an independent bit of information or supposed information in the possession of the State to which the bidder resorted in making the investigations which it was required to make. If it relied upon this paper, it did so at its own risk. The most it could ask for in regard to this information was good faith."

---

[16] Asst. Corporation Counsel, Div. of Contract Litigation, Law Dept., City of New York, New York, N. Y.

Mr. Newton's further statement that "a contractor is not required to make surveys, soundings, or borings to determine whether the information given him in the contract is correct" is equally misleading, especially when compared with his subsequent remark that "A bidder is not usually required to make borings or other sub-surface investigation, particularly if the work has been done by the owner." Mr. Newton's first statement is too broad, for the Court of Appeals of the State of New York has indicated that situations may arise where the contractor might be held responsible for what borings or soundings made by him would have disclosed. The Court said (60):

"He [the bidder] had the opportunity to physically examine the location of the work to be done, and if that called for extensive tests, by way of borings and soundings, that fact, however troublesome, was one he must take into consideration. He had presented to him an agreement, which was precise and strict in its requirements, and which cast upon him the possible risk that all might not be as it appeared, or as estimated by the surveyor. Admittedly, borings and soundings would have revealed the imperfect performance of the previous grading contract, in the leaving of native rock under the surface of the roadway."

Finally, Mr. Newton's discussion of the cases, in which he makes almost constant reference to the wording of particular contract clauses, is inconsistent with his earlier statement that "too much emphasis" can be placed on the wording of the contract, and that "the facts, not the contract clauses, form the real basis" of the Court's decision. It is the writer's belief that the language in the contract is of primary importance, for that is all that the Court may consider in determining whether owner or contractor was, by their agreement, intended for the rôle of risk-bearer. That intent, once determined, is controlling, and the Court is powerless to do anything but enforce it. As the Court said in Johnson vs. City of New York (83):

"In the absence of fraud or mistake, the contract made by the parties, however burdensome it may prove in execution, must govern. It is no excuse that a party to a contract did not foresee a hardship which its operation might entail. It is the function of courts to enforce contracts according to their true intent and meaning and neither to mitigate nor relieve against their operation."

The proposition that Courts of law, in deciding contract disputes, are doing nothing more than enforcing the intent of the parties, as expressed in their agreement, is one which laymen find difficult to comprehend. Judges cannot make a new contract for the parties; nor can they rewrite a contract so as to make it fairer to one party or the other. If (as so many of those taking part in the discussion seem to feel) it is unfair and inequitable to make the contractor assume the risk of unexpected sub-surface conditions, Court decisions which have that result are not the fault of judges but rather of the parties who willingly signed a contract containing language to that effect.

Mr. Martin states that the judicial opinions cited in the paper "are not much concerned with what is fair but, as a lawyer might say, what is fair 'in the light of the contract.'" He is quite right, if by that he means that the Courts cannot decide contract disputes upon general principles of ethics or morality. On the contrary, the Court's "hands are tied down" to the standard of ethics and morality previously fixed and determined by the parties themselves in the contract which they have signed. Although it is true that, in many cases, a contractor is compelled by the Courts to bear the loss resulting from an unexpected sub-surface condition, it is only because he assumed that risk in his contract; and the Courts, much as they might like to, are powerless to relieve him of the consequences of his unprofitable bargain.

When owners, contractors, and engineers realize that the solution of their difficulties lies not in catch-all contract clauses, but in a careful choice of unambiguous language to express their contractual obligations, there will be no occasion to criticize Courts for decisions which simply place the responsibility on the party who agreed to assume it.

Of course, the question as to whether or not it is sound, ethically or economically, for the contractor to assume the risk of unexpected sub-surface conditions (with which the discussion was almost exclusively concerned) is one which belongs more properly within the sphere of the engineer rather than that of the lawyer. There is much force in the arguments of Messrs. Hammond, Molitor, Marsh, Stanley, White, Thompson, and Farwell against making the contractor assume all the risks. On the other hand, there may be circumstances, as Mr. Farwell points out, under which the owner may feel compelled to require the contractor to do so, even if he thereby pays a higher upset price for the completed structure in order to cover the contractor's contingencies.

It is the writer's thesis that, whatever may be the decision reached in any particular case, the contract should express that decision, clearly and fairly, and in no uncertain terms. If a contractor is expected by the owner to assume all risks, he should be definitely advised of that fact so that appropriate allowances can be made in his bid. If he is not to bear the risk, it is to the owner's advantage that this also be made clear, for then the bids received will not be inflated by the contractors' fear of the unknown. In either event, neither party can have cause to complain or to litigate, for each will know the nature and extent of his contract obligations.

However, this ideal contract, in which there is a "clear meeting of the minds," cannot be wished into existence. The preparation of such a contract requires care and precision in the choice of language, a familiarity with the rules of contract interpretation customarily applied by the Courts, and a working knowledge of the fate that typical contract clauses have suffered in previous legal battles.

Realizing that in most instances construction contracts are drawn by engineers and not by lawyers, the writer hoped that his brief summary of the case law on this subject might prove helpful. If the necessity for careful, frank, and forthright contract draftsmanship has been emphasized, and the means to achieve it suggested, the paper may have served some useful purpose.

Paper No. 2066

DESIGN OF CIRCULAR CONCRETE TANKS

BY GEORGE S. SALTER,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. CARL A. ROSENGARTEN, I. K. SILVERMAN, FRANK J. MCCORMICK, H. B. MUCKLESTON, ROBERT B. B. MOORMAN, DANA YOUNG, L. J. MENSCH, JENS EGEDE NIELSEN, LLOYD S. DYSLAND, BASIL SOUROCHNIKOFF, REGIS F. FEY, AND GEORGE S. SALTER.

SYNOPSIS

The object of this paper is to present a rigorous mathematical design analysis of circular concrete tanks that is accurate for shallow tanks of rather large diameters, such as are used for settling purposes, as well as for deeper tanks of small diameter. It is shown that, by fixing the wall at the base so that the liquid pressure is divided between the circular rings and the vertical cantilevers, the magnitude of the maximum ring tension is greatly reduced. For tanks of proportions such as are ordinarily used for settling purposes the maximum ring tension amounts to only about one-quarter to one-third, and the total amount of wall reinforcement to less than one-half of that required were the wall free at the base. Diagrams are presented to facilitate design and an example is given showing their application.

INTRODUCTION

Theoretically, circular tanks having the least perimeter for a given area are the most economical that can be designed. If no restraint were offered at the junction of the wall with the base, the internal liquid pressure would resolve itself into pure tension and the ordinary cylinder theory would obtain for the full height of the wall. It has been quite common practice to design circular tanks for this condition and (although the wall is rigidly connected to the bottom slab) to provide ring reinforcement for the full liquid pressure. As concrete is a material that lends itself inherently to continuity, a logical method of design using this material is one that takes advantage of this action. Circular tanks built of concrete, however, have more or less restraint at the junction of the wall and the footing unless special precautions are taken to eliminate this action.

NOTE.—Published in March, 1939, *Proceedings*.

[1] Subway Structural Designer, Dept. of Subways and Super Highways, Chicago, Ill.

If the tank wall were rigidly fixed at the base, the ring action would be eliminated at the point where the pressure is the greatest, and thus the percentage of ring steel could be reduced; but this restraint of the wall at the base leads to rather complicated load distribution between the circular ring elements and the vertical cantilever elements. The division of the load between these two structural elements is emphasized by the disposition of the reinforcement in the wall. The size and spacing of the vertical bars is determined by the wall moments, due to that portion of the load carried vertically; and the horizontal ring steel is determined by the magnitude of the ring tension. Naturally, the sum of the loads carried vertically and horizontally must equal the total load and pressure on the wall.

Several methods have been presented in endeavors to evaluate the load distribution between the two structural elements but they have either been merely approximations or have been quite difficult to apply. Furthermore, most previous studies, apparently, were based on the condition of rather deep tanks or tanks of small diameter and thus, although they gave approximately correct results for tanks of those proportions, they were decidedly "out of line" for large-diameter, and rather shallow, tanks such as are ordinarily used for settling purposes for sewage, water purification, and certain metallurgical processes.

The purpose of this paper is to present a strictly rigorous analysis and yet one that is easy to apply and which yields results that are accurate, within the limits of the assumptions made, for tanks of any proportions. Although the analysis applies to tanks of all sizes, the diagrams presented herein apply only to tanks of proportions such as are ordinarily used for settling purposes. Of course, these diagrams can be extended to include tanks of all sizes.

ANALYSIS

The following is presented as a rigorous analysis of the problem when the wall is considered as an elastic cylinder, fixed at the base. Given a tank of radius r and height h. With origin at the base of the wall, the internal pressure at any point, due to a liquid whose unit weight is w, is $w(h - x)$, in which x is the distance above the base of the wall.

Consider one-half of a cylindrical tank as represented in Fig. 1(*b*). The vertical strip of height h and width $r\,d\phi$ represents a vertical cantilever element, and the horizontal element of height dh represents one-half of a circular ring element. If the wall is fixed at the base the liquid pressure will be resisted in part by cantilever action and in part by ring action. The distribution of the load between the two elements must be such as to make the deflection of the cantilever equal to the radial displacement of the ring.

Consider first the loading on the circular ring. Fig. 1(*a*) represents one-half of a ring element of height dh, and thickness t. It is subjected to a uniform radial load, which is some part of the liquid pressure, of intensity p_r, and is assumed to be acting on the center line of the ring. Furthermore, the thickness is assumed to be so small compared to the radius that the stress on the cross-sectional area is uniform.

The force acting on an element of the ring is $p_r\,r\,d\phi\,dh$, in which $d\phi$ is the central angle that subtends the vertical strip. Taking the sum of the components of all the radial forces acting on the half ring, the equation of equilibrium is as follows:

$$2\,S = 2\int_0^{0.5\pi} p_r \sin\phi\; r\,d\phi\,dh = 2\,p_r\,r\,dh \quad\ldots\ldots\ldots\ldots(1)$$

and, therefore,

$$S = p_r\,r\,dh \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2)$$

The unit tensile stress is found by dividing the total stress by the cross-sectional area of the ring:

$$f_s = \frac{p_r\,r\,dh}{t\,dh} = \frac{p_r\,r}{t} \quad\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

For a given modulus of elasticity, E_0, of the shell, the elongation becomes $\frac{2\,\pi\,r\,f_s}{E_0}$ and the resultant increase in the radius, denoted by y, is

$$y = \frac{2\,\pi\,r\,f_s}{2\,E_0\,\pi} = \frac{r\,f_s}{E_0} \quad\ldots\ldots\ldots\ldots\ldots\ldots(4)$$

Substituting the value of f_s given in Equation (3)

$$y = \frac{p_r\,r^2}{E_0\,t} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(5)$$

and, therefore,

$$p_r = \frac{E_0\,t}{r^2}\,y \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(6)$$

Next, consider a vertical strip, of width $r\,d\phi$ and height h, also as indicated in Fig. 1(*b*). The total liquid pressure is represented by the triangle in Fig. 1(*c*) and this is divided into two parts by the "load-distribution curve" *A E D*. The cross-hatched area represents that part of the load resisted by the cantilever, and the algebraic sum of the loads on the cantilever and the ring must equal the liquid pressure; that is,

$$p_c + p_r = w\,(h - x) \quad\text{(7a)}$$

or

$$p_c = w\,(h - x) - p_r \quad\text{(7b)}$$

Substituting the value of p_r, as given in Equation (6), in Equation (7*b*), the load on the cantilever may be expressed as

$$p_c = w\,(h - x) - \frac{E_0\,t}{r^2}\,y \quad\text{(8)}$$

The general differential equation of the elastic curve of a beam under any system of continuous loading is expressed[3] by

$$E\,I\,\frac{d^2y}{dx^2} = M \quad\text{(9a)}$$

in which M = moment at any point; also,

$$\frac{dy}{dx} = \theta \quad\text{(9b)}$$

$$E\,I\,\frac{d^3y}{dx^3} = V \quad\text{(9c)}$$

and

$$E\,I\,\frac{d^4y}{dx^4} = p_c \quad\text{(9d)}$$

in which θ, V, and p_c equal slope, shear, and unit load, respectively. Substituting in Equation (9*d*) the value of p_c given in Equation (8)

$$E\,I\,\frac{d^4y}{dx^4} = w\,(h - x) - \frac{E_0\,t}{r^2}\,y \quad\text{(10a)}$$

or

$$\frac{d^4y}{dx^4} + \frac{E_0\,t}{r^2\,E\,I}\,y = \frac{w\,(h - x)}{E\,I} \quad\text{(10b)}$$

The general solution of Equation (10*b*) is[4]

$$y = e^{\beta x}\,(A \cos \beta\, x + B \sin \beta\, x) + e^{-\beta x}\,(C \cos \beta\, x + D \sin \beta\, x) + \frac{w\,(h - x)\,r^2}{E_0\,t} \quad\text{(11)}$$

in which A, B, C, and D are arbitrary constants whose values must be determined from known conditions at certain points; e is the base of Naperian logarithms; E_0 = modulus of elasticity of the reinforced circular rings,

---

[3] "Strength of Materials," by S. Timoshenko, Part I, p. 182.

[4] *Loc. cit.*, Part II, p. 402.

E = modulus of elasticity of the reinforced vertical cantilevers; I = moment of inertia of the vertical section $= \frac{t^3}{12}$; and,

$$\beta = \sqrt[4]{\frac{E_0\, t}{4\, r^2\, E\, I}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

By successive differentiation of Equation (11) the following equations may be secured:

$$\frac{dy}{dx} = \beta\, e^{\beta x}\,[(A + B)\cos\beta\, x - (A - B)\sin\beta\, x]$$

$$- \beta\, e^{-\beta x}\,[(C - D)\cos\beta\, x + (C + D)\sin\beta\, x] - \frac{w\, r^2}{E_0\, t} \ldots\ldots (13a)$$

$$\frac{d^2y}{dx^2} = 2\,\beta^2\, e^{\beta x}\,(B\cos\beta\, x - A\sin\beta\, x)$$

$$- 2\,\beta^2\, e^{-\beta x}\,(D\cos\beta\, x - C\sin\beta\, x) \ldots\ldots\ldots\ldots (13b)$$

$$\frac{d^3y}{dx^3} = -\,2\,\beta^3\, e^{\beta x}\,[(A - B)\cos\beta\, x + (A + B)\sin\beta\, x]$$

$$+ 2\,\beta^3\, e^{-\beta x}\,[(C + D)\cos\beta\, x - (C - D)\sin\beta\, x] \ldots\ldots\ldots (13c)$$

and,

$$\frac{d^4y}{dx^4} = -\,4\,\beta^4\, e^{\beta x}\,(A\cos\beta\, x + B\sin\beta\, x)$$

$$- 4\,\beta^4\, e^{-\beta x}\,(C\cos\beta\, x + D\sin\beta\, x) \ldots\ldots\ldots\ldots (13d)$$

Under the condition of base fixed and top free, the slope and deflection are zero at the base of the wall where $x = 0$, whereas, at the top of the wall where $x = h$, the moment and shear are zero. Thus, by setting, for the proper values of x, the appropriate one of Equations (13) equal to zero, and solving, the values of the four arbitrary constants may be determined, and are expressed as follows:

$$A = \frac{w\, r^2}{\beta\, E_0\, t}\left\{\frac{e^{2\theta}\,[2\cos^2\theta + \theta\,(\sin 2\,\theta + \cos 2\,\theta - 4\cos^2\theta)] - \theta}{(1 + e^{2\theta})^2 + 4\, e^{2\theta}\cos^2\theta}\right\} = F\, C_1 \ldots (14a)$$

$$B = \frac{w\, r^2}{\beta\, E_0\, t}\left\{\frac{1 + \theta + e^{2\theta}\,[1 + \sin 2\,\theta - \theta\,(\cos 2\,\theta + \sin 2\,\theta)]}{(1 + e^{2\theta})^2 + 4\, e^{2\theta}\cos^2\theta}\right\} = F\, C_2 \ldots (14b)$$

$$C = -\,F\,(C_1 + \theta) \ldots\ldots\ldots\ldots\ldots\ldots (14c)$$

and,

$$D = F\,(1 - \theta - 2\, C_1 - C_2) \ldots\ldots\ldots\ldots (14d)$$

in which,

$$\theta = \beta\, h \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15a)$$

and,

$$F = \frac{w\, r^2}{\beta\, E_0\, t} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15b)$$

It may be readily seen that there is only one variable in Equations (14) so that for any given value of this term the expression in brackets has a definite value. Thus, by allotting values to θ at regular intervals, it is best to express these values in terms of π so as to facilitate computations; the values of the arbitrary constants may be determined, and thus by substitution in Equations (13*b*), (13*c*), and (13*d*), the moment, shear, and load, for any value of θ, at any wall height, may be determined. In Fig. 2, Functions C_1 and C_2 are shown graphically.

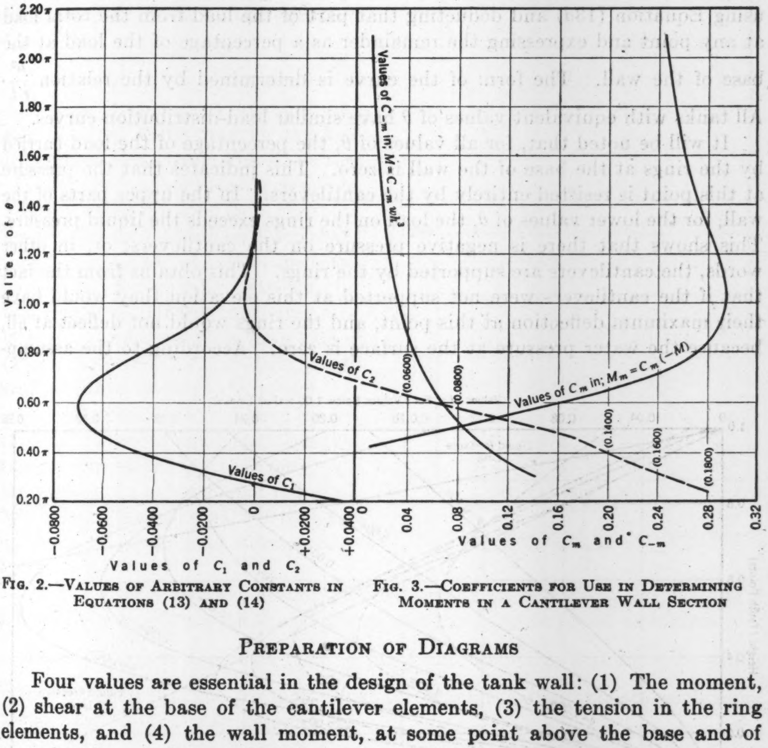

FIG. 2.—VALUES OF ARBITRARY CONSTANTS IN EQUATIONS (13) AND (14)

FIG. 3.—COEFFICIENTS FOR USE IN DETERMINING MOMENTS IN A CANTILEVER WALL SECTION

PREPARATION OF DIAGRAMS

Four values are essential in the design of the tank wall: (1) The moment, (2) shear at the base of the cantilever elements, (3) the tension in the ring elements, and (4) the wall moment, at some point above the base and of opposite sign to that at the base, due to the upper ring elements supporting the cantilevers.

By the use of Equation (13*b*) curves were plotted for the various values of θ, by which the moment at any height of the wall could be determined. However, as the moments at only two points are needed in the design, the negative moment at the base, and the positive moment at some point above the base, those curves were used to prepare the curves given in Fig. 3. In Fig. 3 the value of C_{-m}, cantilever negative moment coefficient, increases for diminishing values of θ, becoming 0.167 when θ becomes 0, the limiting case when the wall is a pure cantilever. The curve for C_m in Fig. 3 shows that the maximum value of the ratio of the positive moment to the negative moment occurs for a θ-value of approximately 1.0 π, and amounts to about 29.4% of the negative moment. This percentage decreases rapidly for θ-values below 1.0 π and less rapidly for θ-values above 1.0 π.

Fig. 4 gives the "load-distribution curves" for values of θ from 0.40 π to 2.00 π. The curves give the load carried by the circular rings, expressed as a percentage of the pressure at the base of the wall. These values were determined for the values of θ indicated by finding the load on the cantilever using Equation (13*d*) and deducting that part of the load from the total load at any point and expressing the remainder as a percentage of the load at the base of the wall. The form of the curve is determined by the relation $\frac{h^2}{r\,t}$. All tanks with equivalent values of θ have similar load-distribution curves.

It will be noted that, for all values of θ, the percentage of the load carried by the rings at the base of the wall is zero. This indicates that the pressure at this point is resisted entirely by the cantilevers. In the upper parts of the wall, for the lower values of θ, the load on the rings exceeds the liquid pressure. This shows that there is negative pressure on the cantilevers; or, in other words, the cantilevers are supported by the rings. This obtains from the fact that if the cantilevers were not supported at this elevation they would have their maximum deflection at this point, and the rings would not deflect at all, because the water pressure at the surface is zero. According to the assumptions of this paper the displacements of the rings and the cantilevers at all points are equal, and thus the rings at the higher elevations support not only the direct liquid pressure but also some load coming to them from the vertical cantilever elements. For the higher values of θ, the load on the rings in the upper parts of the wall is practically equal to the liquid pressure, as the curves

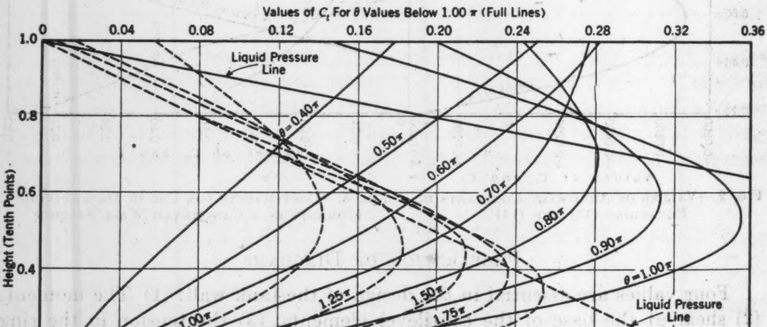

FIG. 4.—TENSION IN CIRCULAR RINGS ($T = C_t\,w\,h\,r$)

show. This indicates that for the deeper tanks, or for those of smaller diameter, restraint at the base has little or no effect at the upper parts of the wall, as would be expected.

The shear is determined by use of Equation (13c). The coefficient for determining its value has been plotted in Fig. 5 and for ease of application has been expressed in percentages of the total load; thus, the shear at the base of the wall is found by the equation

$$V = C_v \frac{w\,h^2}{2} \ldots\ldots (16)$$

Although computed by use of Equation (13c) its value may be checked by determining, from Fig. 4, values of C_t for the load on the ring elements and deducting this load from the total liquid pressure. It will be noted that, for a θ-value of about $1.08\,\pi$, the total load is divided equally between the ring elements and the cantilever elements. For θ-values less than $1.08\,\pi$ (which will include practically all shallow tanks of large diameter) the load on the cantilever will be in excess of 50% of the total load, and thus the ring tension will be less than 50% and the total ring reinforcement required will be less than one-half of that required if all of the load were carried by the rings.

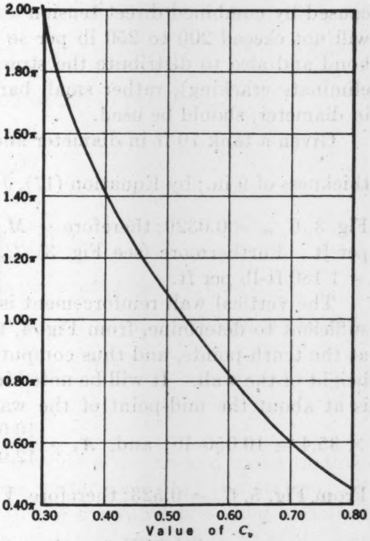

FIG. 5.—COEFFICIENTS FOR USE IN DETERMINING SHEAR AT BASE OF WALL

It is desirable to have a simplified expression to determine the value of θ for use in connection with the diagrams and this may be found as follows:

Substituting, in Equation (12), $\frac{t^3}{12}$ for I and assuming that $E_0 = E$, which is approximately correct for most tanks for which the diagrams are applicable, the expression for θ may be given as,

$$\theta = \frac{h}{\pi}\sqrt[4]{\frac{3}{r^2\,t^2}} = h\sqrt{\frac{0.176}{r\,t}} \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

Note that the value of θ is expressed in terms of π and it is so indicated on the diagrams.

EXAMPLE

The use of the diagrams in design will be demonstrated by a numerical example. Certain conditions have been assumed in the analysis, and the designer should consider how closely the actual conditions fulfill these requirements. The most important are: The degree of restraint at the base of the wall; the moment of inertia of the reinforced section; the modulus of elasticity of the concrete; and the extent to which the concrete itself resists tension.

As in most structures where water-tightness is required, a rather rich concrete should be specified, and to reduce cracking, a low stress in the ring steel should be used; 12 000 lb per sq in. is recommended. The percentage of the ring reinforcement should be limited so that the tensile stress in the concrete, caused by combined direct tension and contraction due to curing and drying, will not exceed 200 to 250 lb per sq in. In order to secure better values in bond and also to distribute the stresses properly (both of which will help to eliminate cracking), rather small bars, preferably those not exceeding ⅝ in. in diameter, should be used.

Given a tank 70 ft in diameter and a water depth of 12.5 ft, assume a wall thickness of 9 in.; by Equation (17), $\theta = 12.5\sqrt{\dfrac{0.176}{35.4 \times 0.75}} = 1.018\,\pi$. From Fig. 3, $C_{-m} = 0.0329$; therefore $-M = 0.0329 \times 62.5 \times (12.5)^3 = 4\,020$ ft-lb per ft. Furthermore (see Fig. 3), $C_m = 0.294$; therefore $M = 0.294 \times 4\,020 = 1\,180$ ft-lb per ft.

The vertical wall reinforcement is determined from these moments. It is sufficient to determine, from Fig. 4, the values of the ring tension coefficients at the tenth-points, and thus compute the percentage of ring steel for the full height of the wall. It will be noted in Table 1 that the maximum ring tension is at about the mid-point of the wall; that is, $T_{\max} = 0.364 \times 62.5 \times 12.5 \times 35.4 = 10\,050$ lb; and, $A_s = \dfrac{10\,050}{12\,000} = 0.84$ sq in. per ft of wall height. From Fig. 5, $C_v = 0.523$; therefore, $V = 0.523\,\dfrac{62.5 \times (12.5)^2}{2} = 2\,560$ lb per ft.

TABLE 1.—COMPUTATION OF RING STEEL

Tenth-points with Point 1.0 at the top (1)	Coefficient C_t (2)	Ring tension, in pounds per foot of wall height (3)	Area of steel, A_s, in square inches per foot of height (4)	Tenth-points with Point 1.0 at the top (1)	Coefficient C_t (2)	Ring tension, in pounds per foot of wall height (3)	Area of steel, A_s, in square inches per foot of height (4)
1.0	0.137	3 780	0.32	0.5	0.364	10 050	0.84
0.9	0.204	5 640	0.47	0.4	0.334	9 220	0.77
0.8	0.266	7 350	0.62	0.3	0.262	7 240	0.61
0.7	0.322	8 890	0.74	0.2	0.158	4 360	0.37
0.6	0.356	9 820	0.84	0.1	0.053	1 460	0.12

The wall should be investigated for external pressures in the same manner. For earth loading this may be done by substituting for the earth pressure an equivalent fluid; and, if the external loading extends to either a greater or less height than the internal loading, also substitute the revised value for the height. For external loading the rings are in compression and thus do not require reinforcement.

The wall thickness should be checked to make certain that the tension stress in the concrete is not excessive. The curing stress may be determined from the usual formula.[5]

$$f_c = \frac{C\,E_c\,n\,p}{1 + n\,p} \quad \text{(18)}$$

in which C = coefficient of contraction of the concrete, assumed as 0.0003. Use the transformed section to find the stress in the concrete due to the ring tension:

$$f_t = \frac{T}{A_c\,(1 + n\,p)} \quad \text{(19)}$$

The sum of f_c and f_t should not exceed 200 to 250 lb per sq in.:

$$f_c = \frac{0.0003 \times 2\,500\,000 \times 12 \times 0.0077}{1 + 12 \times 0.0077} = 64$$

and

$$f_t = \frac{10\,050}{9 \times 12\,(1 + 12 \times 0.0077)} = \underline{85}$$

and, total stress, in pounds per square inch = 149.

The 9-in. wall is adequate. Note that 0.0077 is the maximum percentage of the ring reinforcement; that is, $p = \frac{0.84}{9 \times 12} = 0.0077$.

CONCLUSION

It is intended that this paper should provide a simple and direct method of designing circular concrete tanks. The writer feels that the accuracy of the rigorous analysis has been retained in the diagrams presented and that by their use circular concrete tanks can be designed, not only more easily, but also more economically, than with the approximate or rule-of-thumb methods now commonly in use.

ACKNOWLEDGMENT

The paper is based upon a thesis entitled "The Design of Circular Concrete Tanks," presented by the writer to the University of Nebraska in 1937, in partial fulfillment of the requirements for the professional degree of Civil Engineer.

---

[5] "Principles of Reinforced Concrete Construction," by F. E. Turneaure, Hon. M. Am. Soc. C. E., and Ward B. Maurer, Assoc. M. Am. Soc. C. E., Third Edition, p. 36.

DISCUSSION

Carl A. Rosengarten,[6] **Assoc. M. Am. Soc. C. E.** (by letter).—Although a circular concrete tank is economical so far as having the least perimeter for a given area, it would obviously be extravagant if it were designed only as a common cylinder with all stresses taken by the steel, and if a perfectly good structural material, such as concrete, were used merely as a filler. A design that utilizes the structural properties of the concrete more efficiently, therefore, should be more economical, as demonstrated in Mr. Salter's paper in which he considers the lower part of the wall to act as a cantilever.

However, if the wall were considered as bending vertically for its full height from a fixed-end condition at the base, to a supporting ring of tension steel at the top, the concrete would be utilized to a still greater extent as more of the wall would be stressed in bending. Water-tightness can be improved by pre-stressing the steel tension ring at the top which, again, is made possible by increasing the use of the concrete in compression.

In designing concrete tanks of various shapes, the writer has found that, wherever it is possible to secure a support at the top of the wall, it is generally more economical to design the wall spanning vertically. This is usually true because the triangular loading of liquid pressure is peculiarly adapted to this condition. The greater part of the load (two-thirds) goes to the bottom of the wall where the floor is already available as a support, leaving only one-third of the load to be taken care of by beams or ties at the top. A fixed-end condition at the base provides a still more favorable distribution of load, giving a reaction of four-fifths of the load at the bottom and one-fifth at the top.

Without attempting to check the rigorous mathematical analysis, the writer notes, in Mr. Salter's illustrative example, that he has determined the area of ring steel by dividing ring tension by a constant unit stress of 12 000 lb per sq in. The stretch or elongation of the steel in the tension rings varies from a maximum near the top of the wall to a theoretical zero at the bottom, according to the deflection of the cantilever wall. According to the fundamental theory that the stress is proportional to the strain or elongation, the unit stress in the ring steel must also vary from a maximum for the rings near the top of the wall to zero for a ring at the bottom.

Since the distribution of stress in any two-way system is complicated by many variables, it would seem advantageous to simplify designs wherever possible without sacrificing economy. In the case of relatively low tanks this can be accomplished by considering the wall as a one-way slab, spanning vertically from a fixed-end condition at the base to a support at the top consisting of a pure tension ring. If this ring is not pre-stressed, adjustment to the vertical steel can be made for the deflection (or, settlement of support) caused by the elongation of the top ring steel.

---

[6] Architectural Engr., The Ballinger Co., Philadelphia, Pa.

I. K. Silverman,[7] Assoc. M. Am. Soc. C. E. (by letter).—It is interesting to note that the problem discussed by Mr. Salter is a special case of a more general problem which includes the arch dam. The solution of the problem of the cylindrical tank has been known and used for many years, its first solution being given by H. Müller-Breslau.[8]

The author has neglected the Poisson effect which is equivalent to assuming that m (Poisson's number) is equal to infinity. Equation (10*b*), however, can be obtained from Müller-Breslau's solution by inserting $\mu = \frac{1}{m} = 0$. The type of formula exemplified by Equation (10*b*) appears throughout engineering literature in the discussion of problems of beams on elastic foundations, and therefore puts the problem of the circular tank in that category. Thus, the cantilever elements carry the difference between the water load and the reaction furnished by the ring elements. This reaction is proportional to the value of the deflection y. This statement is expressed by Equation (10*b*). The arch dam subjected to water load is amenable to the same method of attack, and the trial-load method for the analysis of arch dams is based on the equating of the deflections of the horizontal (arch) elements to those of the vertical (cantilever) elements. The loads on the cantilever elements are similar to that shown in Fig. 1.

Due to symmetry, the forces acting on an element in a cylindrical tank of varying wall thickness are as shown in Fig. 6. The equations of equilibrium are as follows:

Equilibrium against moment:

$$Q = -\frac{dM}{dz} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20a)$$

equilibrium in the radial direction:

$$-\frac{dQ}{dz} + \frac{T}{r} = w\,z \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20b)$$

and, equilibrium in the vertical direction:

$$\frac{dS}{dz} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20c)$$

The movement in the radial direction is denoted by y. The corresponding movement in the vertical direction is given by "u." The strains in the radial and vertical directions are accordingly defined as:

DISCUSSION

Carl A. Rosengarten,[6] Assoc. M. Am. Soc. C. E. (by letter).—Although a circular concrete tank is economical so far as having the least perimeter for a given area, it would obviously be extravagant if it were designed only as a common cylinder with all stresses taken by the steel, and if a perfectly good structural material, such as concrete, were used merely as a filler. A design that utilizes the structural properties of the concrete more efficiently, therefore, should be more economical, as demonstrated in Mr. Salter's paper in which he considers the lower part of the wall to act as a cantilever.

However, if the wall were considered as bending vertically for its full height from a fixed-end condition at the base, to a supporting ring of tension steel at the top, the concrete would be utilized to a still greater extent as more of the wall would be stressed in bending. Water-tightness can be improved by pre-stressing the steel tension ring at the top which, again, is made possible by increasing the use of the concrete in compression.

In designing concrete tanks of various shapes, the writer has found that, wherever it is possible to secure a support at the top of the wall, it is generally more economical to design the wall spanning vertically. This is usually true because the triangular loading of liquid pressure is peculiarly adapted to this condition. The greater part of the load (two-thirds) goes to the bottom of the wall where the floor is already available as a support, leaving only one-third of the load to be taken care of by beams or ties at the top. A fixed-end condition at the base provides a still more favorable distribution of load, giving a reaction of four-fifths of the load at the bottom and one-fifth at the top.

Without attempting to check the rigorous mathematical analysis, the writer notes, in Mr. Salter's illustrative example, that he has determined the area of ring steel by dividing ring tension by a constant unit stress of 12 000 lb per sq in. The stretch or elongation of the steel in the tension rings varies from a maximum near the top of the wall to a theoretical zero at the bottom, according to the deflection of the cantilever wall. According to the fundamental theory that the stress is proportional to the strain or elongation, the unit stress in the ring steel must also vary from a maximum for the rings near the top of the wall to zero for a ring at the bottom.

Since the distribution of stress in any two-way system is complicated by many variables, it would seem advantageous to simplify designs wherever possible without sacrificing economy. In the case of relatively low tanks this can be accomplished by considering the wall as a one-way slab, spanning vertically from a fixed-end condition at the base to a support at the top consisting of a pure tension ring. If this ring is not pre-stressed, adjustment to the vertical steel can be made for the deflection (or, settlement of support) caused by the elongation of the top ring steel.

---

[6] Architectural Engr., The Ballinger Co., Philadelphia, Pa.

I. K. SILVERMAN,[7] ASSOC. M. AM. SOC. C. E. (by letter).—It is interesting to note that the problem discussed by Mr. Salter is a special case of a more general problem which includes the arch dam. The solution of the problem of the cylindrical tank has been known and used for many years, its first solution being given by H. Müller-Breslau.[8]

The author has neglected the Poisson effect which is equivalent to assuming that m (Poisson's number) is equal to infinity. Equation (10*b*), however, can be obtained from Müller-Breslau's solution by inserting $\mu = \frac{1}{m} = 0$. The type of formula exemplified by Equation (10*b*) appears throughout engineering literature in the discussion of problems of beams on elastic foundations, and therefore puts the problem of the circular tank in that category. Thus, the cantilever elements carry the difference between the water load and the reaction furnished by the ring elements. This reaction is proportional to the value of the deflection y. This statement is expressed by Equation (10*b*). The arch dam subjected to water load is amenable to the same method of attack, and the trial-load method for the analysis of arch dams is based on the equating of the deflections of the horizontal (arch) elements to those of the vertical (cantilever) elements. The loads on the cantilever elements are similar to that shown in Fig. 1.

Due to symmetry, the forces acting on an element in a cylindrical tank of varying wall thickness are as shown in Fig. 6. The equations of equilibrium are as follows:

Equilibrium against moment:

$$Q = -\frac{dM}{dz} \quad \text{(20a)}$$

equilibrium in the radial direction:

$$-\frac{dQ}{dz} + \frac{T}{r} = w\,z \quad \text{(20b)}$$

and, equilibrium in the vertical direction:

$$\frac{dS}{dz} = 0 \quad \text{(20c)}$$

The movement in the radial direction is denoted by y. The corresponding movement in the vertical direction is given by "u." The strains in the radial and vertical directions are accordingly defined as:

Carpenter, April, 1927, and June, 1929; "Reinforced Concrete Reservoirs and Tanks," by W. S. Gray, London, pp. 11–15; and "Arched Dams," by B. A. Smith, *Transactions*, Am. Soc. C. E., Vol. 83 (1919–1920), p. 2027.

Radial—

$$\epsilon_1 = \frac{y}{r} \dots\dots\dots\dots\dots\dots\dots\dots (21a)$$

and, vertical

$$\epsilon = \frac{du}{dz} \dots\dots\dots\dots\dots\dots\dots\dots (21b)$$

From the generalized Hooke's law the stress on the element in the vertical direction is

$$\frac{S}{t} = \frac{E}{(1 - \mu^2)} (\epsilon + \mu\, \epsilon_1) \dots (22a)$$

The tangential hoop stress is

$$\frac{T}{t} = \frac{E_0}{(1 - \mu^2)} (\epsilon_1 + \mu\, \epsilon) \dots (22b)$$

in which μ = Poisson's ratio = $\frac{1}{4}$ to $\frac{1}{6}$ for concrete. From considerations of curvature

$$M = \frac{E\, I}{(1 - \mu^2)} \frac{d^2y}{dz^2} \dots (23)$$

Integrating Equation (20c), using the free boundary condition at $z = 0$, together with Equations (21) and (22a), $S = 0$, or

$$\epsilon + \mu\, \epsilon_1 = \frac{du}{dz} + \mu \frac{y}{r} = 0 \;. (24)$$

Using Equations (20a), (20b), (23), and (24) the differential equation for the radial movement, y, is as follows:

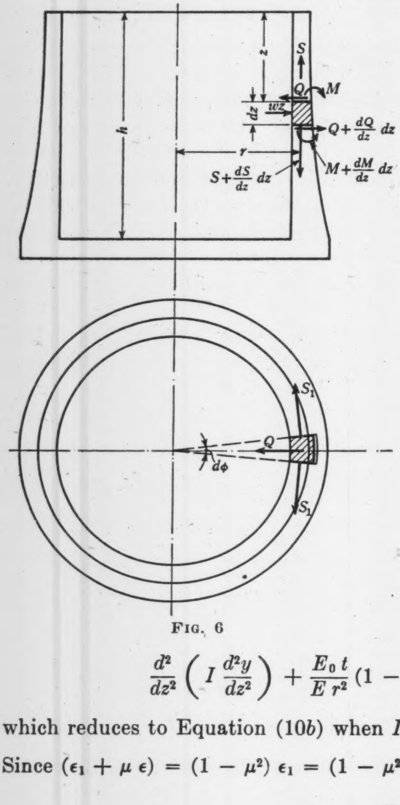

FIG. 6

$$\frac{d^2}{dz^2}\left(I \frac{d^2y}{dz^2}\right) + \frac{E_0\, t}{E\, r^2} (1 - \mu^2)\, y = \frac{w\, z\, (1 - \mu^2)}{E} \dots\dots\dots (25)$$

which reduces to Equation (10b) when I is constant and $\mu = 0$, $z = (h - x)$. Since $(\epsilon_1 + \mu\, \epsilon) = (1 - \mu^2)\, \epsilon_1 = (1 - \mu^2) \frac{y}{r}$ the hoop tension is

$$T = \frac{E_0\, t}{r}\, y \dots\dots\dots\dots\dots\dots\dots\dots (26)$$

so that the unit tensile hoop stress is proportional to the radial movement y.

When the walls of the tank have a triangular section, Equation (25) can be integrated in terms of Bessel functions as shown by F. Tölke.[9] For a trapezoidal section or one bounded by a parabola and a straight line approximate methods are available.[10]

FRANK J. MCCORMICK,[11] ESQ. (by letter).—The author's repeated statement that he has presented a strictly rigorous analysis is open to question, because an analysis based on the assumption of ring stress uniformly distributed over the thickness of the wall is not strictly rigorous except for very thin walls. However, for a wall of homogeneous elastic material, it can be shown that his assumption is justified, in the design of tanks of usual proportions, by making use of Lamé's theory of thick-walled cylinders as described by Professor Timoshenko.[12, 13] He shows that the ring stress in the wall of a circular cylinder subjected to internal pressure is given by the expression

$$f_s = b \times \frac{a^2\,p}{b^2 - a^2}\left(1 + \frac{b^2}{r^2}\right) \quad \text{(27)}$$

in which: a = the internal radius of the tank; b = the external radius of the tank; and r = the radius at which f_s is given by Equation (27). Equation (27) indicates maximum ring stress at the inner surface of the wall, and it is easy to determine that the ratio of the maximum stress to the minimum stress at any section is given by the expression

$$\frac{\text{Maximum}\, f_s}{\text{Minimum}\, f_s} = \frac{a^2 + b^2}{2\,a^2} \quad \text{(28)}$$

For the tank used in the author's example, $\frac{b}{a} = \frac{35.75}{35} = 1.0214$; and, $\frac{\text{Maximum}\, f_s}{\text{Minimum}\, f_s} = 1.021$, which indicates a variation of only 2.1% in the stress across any section. For $\frac{b}{a} = 1.1$ the variation is found to be only $10\frac{1}{2}$ per cent.

The position of the resultant, S, may be derived by writing the moment of f_s about the center of the tank,[14] integrating throughout the thickness of the wall, and dividing this quantity by the total stress, S. Thus,

$$r_s = \frac{\int f_s\, r\, dr}{\int f_s\, dr} = b \times \frac{\frac{1}{2}\left[1 - \left(\frac{a}{b}\right)^2\right] + \log_e \frac{b}{a}}{\frac{b}{a} - \frac{a}{b}} \quad \text{(29)}$$

in which r_s = the radius to the resultant total stress, S. In the author's example, $\frac{b}{a} = 1.0214$ and from Equation (29) $r_s = 34.3737$ ft. The distance from the center of the wall to the point of action of the resultant stress, S, is then only 0.0156 in., or 0.0017 t. The tacit assumption by the author, that there is no moment on a vertical section and that the stress is uniformly distributed across the section, may thus be justified.

For a tank wall the flexural rigidity is more accurately represented by the expression $\frac{E\,t^3}{12\,(1 - \mu^2)}$ (in which μ = Poisson's ratio) rather than by the author's[15] term $\frac{E\,t^3}{12}$. Because of the uncertainty involved in the evaluation of this quantity for reinforced concrete, and because the value usually chosen for μ is small (less than 0.25) probably no serious error results from the use of the simpler expression.

[12] "Strength of Materials," by S. Timoshenko, Part II, p. 531.

[13] "Über die Spannungsverteilung in zylindrischen Behälterwänden," by H. Reissner, *Beton und Eisen*, B. 7, H. VI, 1908, p. 150.

[14] *Loc. cit.*, p. 151.

After evaluation of the constants in Equations (14) by the introduction of the boundary condition, $y = 0$ at $x = 0$, the author later discovers no ring stress at the base of the wall. This, he concludes, indicates that the pressure at this point is resisted entirely by the cantilevers. Any other conclusion would be much more alarming, as this result is implicit in the boundary condition just mentioned, and merely indicates the consistency of the intervening mathematics.

It should be mentioned that Equation (10), and its solution, Equation (11), were published by C. Runge in 1904.[16] H. Reissner extended the solution to include walls of variable thickness in 1908.[13] The latter work, reproduced and further extended by V. Lewe,[17] includes tables and curves to aid in the computation of the radial displacements, ring stresses, and cantilever moments. In part the tables and curves are equivalent to those given by the author in Figs. 3 and 4; but they also include data pertaining to tanks with walls of triangular section as well as to those with walls of constant thickness. In this work, furthermore, may be found a rather incomplete table of constants for use in the analysis of shallow circular tanks with walls of trapezoidal section.

H. B. MUCKLESTON,[18] M. AM. SOC. C. E. (by letter).—Stresses in a circular reinforced concrete tank are analyzed by an interesting method in this paper. In the course of this analysis, the author makes certain simplifying assumptions without which the resulting differential equation probably could not be integrated:

(1) Implicit in Equations (3) and (4), that the area of the ring steel is uniform from bottom to top of the wall;

(2) Implicit in Equations (9) and (17), that the moment of inertia of the elementary cantilevers is uniform from top to bottom (which means that the steel areas in both faces are uniform);

(3) Implicit in Equation (9), that deformation of the cantilever elements from shear may be neglected;

(4) That E and E_0 may be considered as equal; and,

(5) That Poisson's ratio need not be considered.

Although the last three of these may be of small importance, the first two are fundamental and must be closely realized in design or the entire analysis becomes null.

[18] Cons. Engr., Vancouver, B. C., Canada.

In Table 1, the author has adjusted the ring-steel areas to the computed ring stresses on a basis of 12 000 lb per sq in. If the tank were built to these areas, the computed ring stresses could not exist since they were computed on the hypothesis that the steel area was uniform. In fact if they did exist, the deflection y would be uniform from bottom to top, which is contrary to the hypothesis.

Either the ring steel and cantilever steel must be kept uniform (in which case the analysis is applicable), or they may be variable, in which case the analysis does not apply and a solution must be sought by some trial-load method.

If they are kept uniform, there is a question whether a tank so designed will show any economy over a tank of similar dimensions designed according to the simple cylinder hypothesis. In the example the maximum ring steel area is 0.77% of the concrete area. If the hypothesis is to apply, the same proportion must be used for the entire height. The ring steel will then be 0.77% of the entire volume of concrete in the wall. To this must be added the vertical steel which will scarcely be less than 0.75% of the volume. This is a total steel for the wall, amounting to 1.52% of the wall volume.

Using the same wall thickness and steel stress, the ring steel in a design by the simple cylinder hypothesis would require about 1.07% of the wall volume, to which about 0.18% must be added for vertical spacing rods. The difference, for a tank of these dimensions, is not far from 2 700 lb of steel. Moreover, the steel in the latter case would be cheaper to erect, and the wall thickness might well be somewhat less.

It might be argued that leaving the cantilever action out of consideration will result in ring cracks near the base of the wall. It is questionable if experience would bear out this contention. Many tanks have been built on that basis and it is not on record, so far as the writer knows, that even a large proportion of them show such cracks. If they are feared, the steel in the lowest foot might be computed on a basis of, say, 8 000 lb per sq in. That would reduce thc outward deflection to a point where the shear resistance of the concrete could take care of it easily. In the case in question, the outward movement, if there were a smooth, frictionless joint at the base, would be only about 0.0117 in.

ROBERT B. B. MOORMAN,[19] ASSOC. M. AM. SOC. C. E. (by letter).—This paper is a very worth while contribution to American engineering literature on the subject of circular concrete tanks. In England W. S. Gray has published two books[20, 21] on the design of reinforced concrete tanks and water-towers. The information on the analysis of circular tanks in these two books was obtained from an earlier publication[22] by H. Carpenter explaining the method by H. Reissner.[23]

[22] *Concrete and Constructional Engineering*, Concrete Publications Limited, London, England, Vol. 22, April, 1927, p. 237, and Vol. 24, June, 1929, p. 345.

[23] "Handbuch für Eisenbetonbau," Vol. V.

Figs. 2, 3, and 4, however, are more comprehensive. According to Reissner's theory all tanks with equivalent K-values $\left(K = \frac{12\,h^4}{r^2\,t^2}\right.$, in which r = radius of inside of tank$\left.\right)$ have similar load-distribution curves. This K-value is similar to the author's θ^4. The author bases his curves on equivalent θ-values, whereas the curves presented by Gray are based on equivalent K-values.

Equation (17) would be understood more clearly if it were written

$$\theta = \frac{h}{\pi}\sqrt[4]{\frac{3}{r^2\,t^2}}\,\pi = h\sqrt{\frac{0.176}{r\,t}}\,\pi \;\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

This equation may be simplified further by letting $R\,h = r$ and $T\,h = t$ and writing the expression for θ as

$$\theta = \frac{0.419}{\sqrt{R\,T}}\,\pi \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

The work involved in computing θ by use of Equation (30) or (31) would probably be about the same when reviewing a tank of given dimensions. However, Equation (31) is more flexible in that only relative dimensions are needed to compute the value of θ.

Using the data of the author's example, the bending moment (both positive and negative) and shear are computed as follows:[20] Since the curves presented by Gray are for values of K equal to 0, 10, 100, 1 000, and 10 000, only a rough check can be expected. For this example

$$K = \frac{12\,(12.5)^4}{(35)^2\,(0.75)^2} = 425.$$

Upon sketching a curve for $K = 425$,[24] values are obtained for the coefficient, C_t, by use of which the ring tension can be computed in pounds per foot of wall height (see Table 2).

TABLE 2.—COMPUTATION OF RING TENSION

Description	TENTH-POINTS, WITH POINT 1.0 AT THE TOP										Average
	1.0	0.9	0.8	0.7	0.6	0.5	0.4	0.3	0.2	0.1	
Coefficient, C_t	0.13	0.18	0.27	0.31	0.36	0.37	0.33	0.25	0.15	0.06	0.241
Ring tension, in pounds per foot of wall height	3 560	4 920	7 390	8 480	9 850	10 120	9 030	6 840	4 100	1 640	....

A coefficient[25] $C_{-m} = 0.036$ for the negative moment gives $-M = 0.036 \times 62.5 \times (12.5)^3 = 4\,390$ ft-lb per ft. The value of the positive moment is taken as one-fourth to one-third of the negative moment or, using an average of this range, $M = 0.29 \times 4\,390 = 1\,273$ ft-lb per ft.

---

[24] From curves by Carpenter; "The Calculation of Cylindrical Tanks with Rectangular, Triangular or Trapezoidal Wall Sections," by H. Carpenter, *Concrete and Constructional Engineering*, Concrete Publications Limited, London, England, June, 1929, Fig. 2, p. 347.

[25] Selected from curves; *loc. cit.*, Fig. 3, p. 348.

The shear can be obtained by subtracting the portion of the horizontal load carried by the rings from the total horizontal load; or, $V = (0.5 - 0.241)$ $62.5 \times (12.5)^2 = 2\,539$ lb per ft. The use of the coefficient 0.241 is not quite proper since it is the average coefficient for the ring tension at the top of the tenth-points. These values of the positive and negative moments and shear agree fairly well with the author's values.

Although, in practically all cases, Equations (18) and (19) are satisfactory, the more exact expressions are

$$f_c = \frac{C\,E_c\,n\,p}{1 + (n - 1)\,p} \qquad (32)$$

and

$$f_s = \frac{T}{A_c\,[1 + (n - 1)\,p]} \qquad (33)$$

That is, $f_c = 65$, $f_s = 86$, and the total stress is 151 lb per sq in.

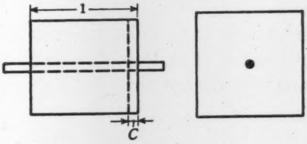

FIG. 7

A derivation of the expression for unit stress in the concrete due to contraction (Equation (32)), which is similar to Equation (19), follows: A steel bar, embedded in concrete, is shown in Fig. 7. The cross-section of the steel is $A\,p$ and of the concrete is $A\,(1 - p)$. In a unit length the concrete tends to shorten a distance C, which is the coefficient of contraction of the concrete. The deformation in the steel must equal the deformation in the concrete, or

$$\frac{f_s}{E_s} = C - \frac{f_c}{E_c} \qquad (34)$$

In order that the system shall be in equilibrium the summation of the horizontal stresses must equal zero, or

$$A\,p\,f_s = A\,(1 - p)\,f_c \qquad (35)$$

from which

$$f_s = \frac{(1 - p)}{p}\,f_c \qquad (36)$$

is obtained. From Equation (34):

$$f_s = C\,E_c\,n - f_c\,n \qquad (37)$$

Equation (32) is derived by combining Equations (36) and (37) and solving for f_c.

DANA YOUNG,[26] ASSOC. M. AM. SOC. C. E. (by letter).—The general analysis of the problem stated in this paper has been developed thoroughly by various European engineers and is presented in standard references such those of Pöschl,[27] Flügge,[28] Love,[29] and Löser and Lewe.[30] However, the work done by the author in determining the constants defined in Equations (14) is of great value in designing relatively shallow tanks.

---

[26] Assoc. Prof. of Civ. Eng., University of Connecticut, Storrs, Conn.

[27] "Berechnung von Behältern," by Th. Pöschl, Berlin, Germany, 1926.

[28] "Statik und Dynamik der Schalen," by W. Flügge, Berlin, Germany, 1934.

[29] "A Treatise on the Mathematical Theory of Elasticity," by A. E. H. Love, Cambridge, England, 1927.

[30] "Behälter," by B. Löser and V. Lewe, in Emperger's *Handbuch für Eisenbetonbau*, Third Edition, Vol. 9, Berlin, Germany, 1934.

Any method of analysis is based on various assumptions which the designer must bear in mind. In this regard it may be of interest to discuss several points in the paper. In Equation (3), the unit tensile stress in the concrete is found by dividing the total stress by the cross-sectional area of the ring. It would be more correct to divide by the area of the transformed section $(1 + n\,p)\,t\,dh$ as the author finally does in Equation (19). Equation (9), which is the formula of flexure for a beam, does not apply strictly to a strip of a plate or shell since the adjoining strips restrain the free transverse deformations. As shown in various references,[31] for the case of a plate or shell the equation of flexure is

$$\frac{E\,I}{1 - \nu^2}\frac{d^2y}{dx^2} = M \qquad (38)$$

in which ν is Poisson's ratio. Hence, using Equation (9) is equivalent to assuming that Poisson's ratio is zero. These corrections would not affect the analysis except that the value of the constant β would then be given by

$$\beta = \sqrt[4]{\frac{E_0\,t\,(1 + n\,p)\,(1 - \nu^2)}{4\,r^2\,E\,I}} \qquad (39)$$

The numerical effect of these corrections would be small except in unusual cases. Furthermore, E_0 will equal E in most cases.

The solution of Equation (10*b*) given by the author is based on the assumption that the tank is of constant cross-section and has the same reinforcement throughout its height; that is, that t and I are constant. Small variations in the percentage of reinforcement probably will not change the results seriously, but caution should be used in any design in which t and I vary considerably. The analysis for such conditions is more complicated, of course, but is well treated in the references of Pöschl[27] and Flügge.[28]

As is clearly stated by the author, the constants determined by Equation (14) are for the case in which the base is completely fixed. The designer must consider carefully whether or not this condition is realized in the tank being designed. If the base is not perfectly restrained against rotation of a vertical element, the negative moment at the base will be less than that calculated, but the values of the maximum ring tension and positive moment will be greater.

It may be well to note that the condition which the author assumes at the top where x equals h—namely, that the shear and moment are zero there—is true only if the water level is exactly at the top of the tank. If this is not so, the part of the tank above the water level exerts a restraint on the deformations at the water level. This effect can be taken care of in the evaluation of the constants, although the numerical work involved would be tedious.

The analysis of a circular tank is simplified when the depth is great, or more accurately, when θ is large (say, greater than π). In this case, it may be assumed that $A = B = 0$, or (what is the same thing) that $C_1 = C_2 = 0$.

---

[31] "Strength of Materials," by S. Timoshenko, New York, N. Y., Part II, 1930, pp. 475 and 517; see also Footnote References 27–30.

Mathematically this follows from the fact that the term in Equation (11) containing these constants represents a damped harmonic wave which starts at the upper boundary and is so rapidly damped that it has little effect on the conditions at the base. Physically, this may be seen from the fact that, in a deep tank, the conditions at the upper boundary will have little effect on those at the base. This is clearly shown in Fig. 2, in which, for values of θ greater than about $1.2\,\pi$, the values of the constants C_1 and C_2 are practically zero. Using this assumption, Equations (14) give $A = B = 0$; $C = -F\,\theta$; and, $D = F\,(1 - \theta)$. Then, further assuming a homogeneous tank of constant thickness and neglecting Poisson's ratio $\left(\text{in which case } \theta = h\sqrt[4]{\dfrac{3}{r^2\,t^2}}\right)$, the moment at the base is found by substituting the foregoing values for the constants in Equation (13*a*). After simplifying, this step reduces to

$$(M)_{x=0} = E\,I\left(\frac{d^2y}{dx^2}\right)_{x=0} = \frac{\theta - 1}{2\,\theta^3}\,w\,h^3 \ldots\ldots\ldots\ldots\ (40)$$

which checks closely with Fig. 3 for values of θ greater than π. Similarly, the shear at the base is found to be

$$(V)_{x=0} = E\,I\left(\frac{d^3y}{dx^3}\right)_{x=0} = \frac{1 - 2\,\theta}{\theta^2}\,\frac{w\,h^2}{2} \ldots\ldots\ldots\ldots\ (41)$$

which checks Fig. 5 for large values of θ. The ring tension for this case is given by

$$T = \frac{E\,t}{r}\,y = w\,h\,r\left\{\left(1 - \frac{x}{h}\right) - e^{-a}\left[\cos\theta\frac{x}{h} + \left(1 - \frac{1}{\theta}\right)\sin\theta\frac{x}{h}\right]\right\} \ldots (42)$$

in which $a = \theta\,\dfrac{x}{h}$. Numerical values computed from Equation (42) for the case, $\theta = 1.5\,\pi$, are given in Table 3.

TABLE 3.—RING TENSION COEFFICIENT C_t FOR $\theta = 1.5\,\pi$

$\frac{x}{h}$	FIXED BASE		PINNED BASE
	From Fig. 4	Computed from Equation (42)	Computed from Equation (46)
1.0	0.02	0.007	0
0.8	0.23	0.229	0.219
0.6	0.44	0.442	0.456
0.4	0.53	0.533	0.647
0.2	0.32	0.323	0.571

To show the effect when the wall at the base is not perfectly fixed, it is interesting to investigate the case in which the wall is pinned at the base. Then the results for partial restraint will lie between those for this case and those for the fixed base. Again assuming that $A = B = 0$, the constants C and D are determined from the condition that the deflection and moment at the base of the wall are zero. Substituting these conditions in Equations

(11) and (13*b*), the values of the constants C and D are found to be $C = -F\,\theta$; and, $D = 0$. Then the bending moment is given by

$$M = E\,I\,\frac{d^2y}{dx^2} = -\,2\,E\,I\,F\,\theta\,\beta^2\,e^{-\beta x}\sin\beta\,x \ldots\ldots\ldots\ldots (43)$$

in which the negative sign indicates that the bending produces compression on the inside fibers; that is, the moment is positive according to the convention used by the author. The maximum numerical value for this moment occurs where $x = \frac{\pi}{4\,\beta}$. Substituting this value of x in the moment equation gives the following for the maximum positive bending moment

$$M = \frac{0.161}{\theta^2}\,w\,h^3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (44)$$

Values of this positive moment are greater than the positive moment in the case of a tank with a fixed base.

The shear at the base is given by

$$(V)_{x=0} = E\,I\left(\frac{d^3y}{dx^3}\right)_{x=0} = -\,2\,E\,I\,\beta^3\,F\,\theta = -\,\frac{1}{\theta}\,\frac{w\,h^2}{2} \ldots\ldots (45)$$

These shears are less than those for the case of a fixed base.

The ring tension for the case of the wall pinned at the base is given by

$$T = \frac{E\,t}{r}\,y = w\,h\,r\left[\left(1 - \frac{x}{h}\right) - e^{-a}\cos\theta\,\frac{x}{h}\right] \ldots\ldots\ldots (46)$$

The maximum ring tension for this case is greater than for a fixed base. For comparison, the ring tension coefficients as computed from Equations (42) and (46) for the case in which $\theta = 1.5\,\pi$ are shown in Table 3, together with the values read from the author's curves in Fig. 4.

L. J. MENSCH,[32] M. AM. SOC. C. E. (by letter).—Among the great number of similar problems occurring in the construction of tanks, grain elevators, ships and submarines, airplanes, arched dams, and beam and flat-slab foundations on yielding soil, the author's paper treats of the simplest case. By no means is it simple to the every-day engineer; very likely the author has spent years in developing the analysis and in computing the data on which Figs. 2, 3, and 4 are based.

This particular problem was solved in connection with the design of high-pressure boilers in 1878.[33] With the introduction of reinforced concrete, many papers appeared on secondary stresses in tanks, domes, and foundations.[34] After 1904 the Society published the most important analytical and experimental investigations ever made on arched dams, which is a vastly more difficult problem.

[34] *Handbook on Reinforced Concrete,* by F. Emperger, Berlin, Germany, 1907, and succeeding editions; Volume Fluessigkeitsbehaelter and other volumes.

American designers will look with awe at the forbidding appearance of Equations (14) and will hesitate to use them because of possible typographical and other errors. Other authors have developed short-cuts and have constructed tables and diagrams.[35] Evidently, the author took cognizance only of the short-cuts published in American literature on the design of circular tanks with a characteristic, $\frac{h^2}{r\,t}$, greater than 10, and, for his own practice, developed a design method for tanks with lower characteristics.

How much confidence do practical engineers and owners have in such involved theories? They have very little, at least in the writer's experience. In all likelihood, the chief engineer or owner will direct the designer to use the same ring steel as if the wall were unrestrained at the bottom and, for greater safety, to use the vertical reinforcement required by this analysis.

Such practice prevailed 30 yr ago (1909) in the design and construction of arched bridges. Laboriously, by the elastic theory, using the summation method, designers determined the moments acting at critical points. They did not use these moments for the design of the arch, but drew the line of pressure for live loads on half of the span after many trials, and made the arch section deep enough so that the line of pressure did not fall outside of the middle third at any point. Many concrete bridges were built at that time which were heavier than stone bridges built many hundreds of years ago, and are still in use. When it became fashionable to use reinforced concrete, an ample supply of patented bars were "thrown in for good measure."

The same conditions may be found even to-day with respect to rigid-frame bridges. Trade associations scatter pamphlets by the ten thousands, praising the summation method. The final result is that such bridges have been built, according to the writer's opinion, for a moment of $\frac{W\,L}{8}$ at the haunches so that nothing serious could happen if the bridge cracked at the center; and sufficient concrete and steel were used in the center so that the bridge could not fail if the haunches or abutments were insufficiently designed.

The author's analysis is based on the assumption that the circular wall is fixed at the bottom, both for rotation and horizontal and vertical movement. This condition is obtainable only in the rare case in which the wall is anchored in a trench of solid rock; in most designs which came to the writer's notice, the designer tried to prevent rotation by a special wide footing beneath the wall and floor. Sometimes the cost of the footing was greater than the cost of the wall. In higher tanks the horizontal force from the water pressure at the bottom of the wall was sufficient to move the wall $\frac{1}{4}$ in., $\frac{1}{2}$ in., and in some known cases 1 in. and more, playing havoc with the ordinarily poorly designed joint between wall and floor, and this practice resulted in serious leakage. The ring stresses become greatly increased due to such movements. If, by some miracle, the wall does not move, it is a practical certainty that there will be a rotation of the wall at the bottom, especially if the footing was skimped in order to save money. Such a rotation will diminish the moment at the base, will increase the positive moment more rapidly, and will also increase ring stresses.

---

[35] *Handbook on Reinforced Concrete,* by F. Emperger, Berlin, Germany, 1907, Third Edition, Vol. 5, 1923, pp. 87–112.

Where a group of tanks is to be built, it is uneconomical to use circular tanks, and covered square tanks may be less costly than open round tanks built separately. In such tanks the walls are computed for top and bottom restraint, and the corner restraints are determined by an analysis similar to that presented by the author.

Domes of large span, covering circular tanks, will exert a large thrust at the top of the wall, resulting in a horizontal movement even at that point, where a heavy ring girder is used to take up the thrust, thereby increasing the ring stresses and causing secondary bending in the walls.

JENS EGEDE NIELSEN,[36] ASSOC. M. AM. SOC. C. E. (by letter).—The author has revived the problem of a cylindrical shell, closed at one end, in its simplest and most practical form where the thickness of the shell is uniform. The general problem was treated in detail by Professor Grashof [37] in 1874. However, his solution of the fourth-order differential equation is not directly applicable to practical use, and the author, therefore, is to be congratulated for offering a solution which embraces most considerations required by the designing engineer.

In order to render "unto Caesar the things which are Caesar's," it is only fair to state that it is an erroneous conclusion of the author that all concrete tanks constructed previous to the appearance of this paper had been designed haphazardly or inefficiently. It has long been known that the shape of the elastic curve is clearly a function of $\frac{h^2}{r\,t}$ as the author correctly states. Based on this fact, it has been possible to make a close approximation of the distribution of the load between the ring and the cantilever, and tables compiled on this basis may be found in offices where concrete water tanks are designed. These tables are probably as efficient as the author's diagrams, and naturally should be so, as they are fundamentally alike.

In water tanks it is important that no cracks develop; otherwise, due to the high internal pressure, water will penetrate and in time destroy the reinforcement and the wall. Experiments at the University of Illinois indicate that a stress of 6 000 lb per sq in. should not be exceeded in order to eliminate destructive hair cracks in the concrete. The author recommends 12 000 lb per sq in. as the proper working stress. Here, then, is a difference of opinion, and designers are again confronted with a method of design more refined than is warranted by other considerations.

If insufficient additional reinforcement is provided to take care of volumetric and temperature changes, as suggested by C. P. Vetter, Assoc. M. Am. Soc. C. E.,[38] and a stress in excess of 6 000 lb per sq in. is permitted, fine hair cracks will develop and, in time, the ring steel will be required to sustain all tension due to continuing diminished adhesion. The modulus of elasticity E_0, therefore, will not be equal to E when this stage has been reached, but will probably be nearer ten times E. Hence, the value of β and θ must be modified and the diagrams adjusted accordingly. In spite of the fact that this is one of the extremely rare cases in engineering where the exact live load is known, designers are confronted with a disturbing uncertainty which, when they are pressed for time, they overcome by "playing safe," providing for the most extreme possibility.

[37] "Theory of Elasticity," by Franz Grashof, Berlin, Germany, 1874.

[38] *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 1039.

It may be opportune here to draw the attention to the importance of continuous operation when placing concrete in the forms. If the operation is interrupted, the finished tank will develop a horizontal leak precisely at that level, and it requires considerable care and expense to correct it afterward. The writer recalls one tank for which the cost was increased several hundred dollars on account of a short lunch period.

This paper is highly meritorious in that it provides an avenue of approach which may be extended at leisure to conform to the individual designer's ideas.

LLOYD S. DYSLAND,[39] JUN. AM. SOC. C. E. (by letter).—This paper provides a distinct advance in accuracy and ease of design of an indeterminate problem of frequent occurrence, particularly by the inclusion of Fig. 4. Unfortunately the plotting of C_{-m} is not consistent with such accuracy. However, it can be calculated from the expression $M = \frac{w\,h^3}{2\,\theta^3}(2\,C_1 + 2\,C_2 + \theta - 1)$, which is derived from Equation (14*a*), by using a value of $\theta = \pi\,h\sqrt{\frac{0.176}{r\,t}}$ and the values of C_1 and C_2 in Fig. 2. A direct means of computing the height of the point of inflection of the wall moment is quite desirable but is not included.

The analysis presented provides for an inside fluid-pressure loading for the entire wall height and may, by a change of sign, be applied to exterior fluid-pressure loads for the entire wall height. However, it cannot be indiscriminately used for loading to any fraction of the wall height, although the author's statement following Table 1 would lead the reader to that conclusion.

From physical considerations it seems that with partial loading, when use of the loaded height gives values of θ less than about $1.0\,\pi$, the mathematical analysis may be seriously misleading. Fig. 4 shows that for values of θ less than $1.0\,\pi$ the "cantilever" effect (the effect more nearly resembles that of a beam fixed at one end and supported at the other than it does a cantilever) induces a considerable circumferential stress at the top of the loaded portion of the wall which is supposed to be the top of the tank. The analysis gives no stress where there is no load; therefore the wall above the loaded height would have no stress. Thus, for shallow tanks, the analysis would indicate that a highly stressed ring of wall existed adjacent to one which carried no load at all. Such a condition is unreasonable.

Actually, when the wall extends some distance above the height of fluid level, the upper part of the wall must provide (in shallow tanks) additional top restraint to the vertical staves. The result will be a redistribution of hoop stress and a decrease in moment at the base.

---

[39] Designer, Consoer, Townsend & Quinlan, Chicago, Ill.

Manning,[40] in an analysis based on the same fundamental equation (Equation (10*b*)), provides charts to give exact values of moment and shear at the base. However, he uses approximations to determine hoop reinforcement in deep tanks and gives no solution for finding hoop reinforcement in shallow tanks. Leeper[41] greatly simplifies his solution of the differential Equation (10*b*) by neglecting certain terms, and by further approximations derives simple algebraic expressions for the design factors.

For the height above the base at which the point of inflection of wall moment occurs, Manning[40] suggests $0.61\sqrt{r\,t}$ and Leeper[41] gives $0.56\sqrt{r\,t}$.

It frequently happens that greater economy can be realized by using a wall cross-section which tapers toward the top. Some conception of the effect of tapering walls can be gathered from an article by H. Carpenter[42] in which he gives load-distribution and base-moment curves for tanks with walls of triangular cross-section and of rectangular cross-section for several shallowness ratios.

To determine the relative economy of fixed-base design, compared with hoop-tension design, a careful estimate was made recently on two 75-ft diameter sewage digestion tanks, 24 ft deep, in which the chief difference (in addition to the redistribution of reinforcement) was a graphite painted copper joint at the base of the wall designed for hoop tension only. The estimate was $2 000 lower on the fixed-base tank.

BASIL SOUROCHNIKOFF,[43] ESQ. (by letter).—In Mr. Salter's numerical example only stresses due to hydrostatic pressure and curing are computed. As the structural stresses are low, the temperature stresses may be expected to be proportionally important. Assume, for instance, that, due to a decrease of temperature, the rings are shortened. The base, being restrained by the foundation, may not undergo the same shortening. For an effective difference of 10° F between the average temperature of the walls and that of the base, a ring, if not restrained by the cantilever, would have the radius decreased by $0.000006 \times 10 \times 35 \times 12 = 0.025$ in. Due to the hydrostatic pressure alone, a ring at mid-height of the tank, if not restrained by the cantilever, would have its radius increased by $\frac{62 \times 6.28 \times 35}{12 \times 9} \times \frac{1}{2\,500\,000} \times 35 \times 12 = 0.021$ in. Therefore, it may be expected that the temperature stress in the cantilever is of the same order of magnitude as the hydrostatic stress.

The stresses due to a difference of temperature between the walls assumed constant throughout, and the base, may be analyzed by the same method as the hydrostatic stresses are analyzed in the paper. For a temperature difference of $T°$ F, the rings, if not restrained by the base, would have the radius decreased by $y_0 = 0.00006\,T \times r$ ft. In this deformation they are restrained by the base. It is seen that the differential equations and their integration are exactly the same as for hydrostatic pressure, with $w = 0$. For the determination of arbitrary constants one may assume at the top that $\frac{d^2y}{dx^2} = 0$; and $\frac{d^3y}{dx^3} = 0$; and at the bottom $y = -y_0$, and a certain arbitrary angular deformation $\alpha_0 = \frac{dy}{dx}$.

[42] "Calculation of Cylindrical Tanks with Rectangular, Triangular, or Trapezoidal Wall Sections," by H. Carpenter, *Concrete and Construction Engineering*, Vol. 24, No. 6, June, 1929, pp. 345–353.

[43] Structural Engr., St. Paul, Minn.

The stress distribution analyzed by Mr. Salter's method is certainly more exact than that obtained by other approximate methods. However, it seems that it can be extended with advantage to take into account the secondary stresses, which may be important.

Regis F. Fey,[44] Jun. Am. Soc. C. E. (by letter).—Progress in circular tank design is aided materially by Mr. Salter's paper. The effect of shell restraint or fixation at the base (a condition which tank designers realized existed, yet hesitated to consider in their designs) has been analyzed very clearly in this paper.

The importance of the type and degree of restraint of the tank wall at the base is somewhat difficult to determine. For a rational design it is reasonable to discount any appreciable horizontal or vertical movement at this point, but it is more difficult to conclude upon a reasonable assumption with respect to rotation about this point. The combined effect of the wall ring tension and the bottom restraint tends to cause a rotation. If the bottom is rigid enough to counteract any rotation, the cantilever effect of the vertical wall segments will come into full effect in carrying their share of the horizontal load; but if the bottom should deflect somewhat, due to the effect of rotation, the load-carrying capacity of the cantilever wall segments will be reduced somewhat. Therefore, considering the wall rigidly attached to the bottom, the degree of restraint may be considered as a function of the rigidity of the bottom.

When investigating a thin circular wall for external pressures, the resultant effects upon the wall are different from those caused by internal pressures. The stresses in the wall may be treated from the standpoint of the flexural rigidity of a ring. For stress investigation a nominal deformation from the true circle should be considered.

The deformation may be either elliptical or in the form of so-called "flat spots" in the wall (Fig. 8). For an elliptical deformation the maximum bending moment is at Point A. Since the ratio of the applied external pressure is small with respect to the critical external pressure at which the ring would collapse (that is, if no

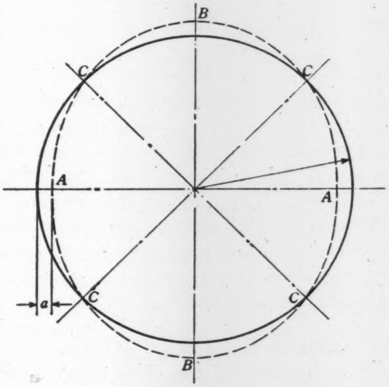

FIG. 8

---

[44] Engr., Pittsburgh Des Moines Steel Co., Pittsburgh, Pa.

further ellipticity would result from the applied external pressure), the moment at Point A is

$$M_A = h\,q\,a\left(r + \frac{a}{2}\right) \qquad (47a)$$

in which, in addition to the notation of the paper: q = the applied pressure; and, a = radial displacement = one-half "out-of-roundness"; that is, one-half the difference between the diameter of the true circle and the minimum diameter of the irregular section. The moment at Point B is in the opposite direction:

$$M_B = h\,q\,a\left(r - \frac{a}{2}\right) \qquad (47b)$$

Since a is small compared with r, the moments at Points A and B may be considered equal for all practical purposes, or:

$$M_A = M_B = h\,q\,a\,r \qquad (48)$$

The moments at Points C are zero.

So called "flat spots" in the circular wall are not plane surfaces but sections which have a lesser degree of curvature. For moment computations a section of wall including, and adjacent to, a flat spot may be considered elliptical in shape. Treating the section as before, the maximum moment at the center of the flat spot will be that given by Equation (48). In this case, however, the radial displacement, a, is equal to the "out-of-roundness." The designer should determine whether care will be taken to prevent any localized irregularities in building the wall section. If this cannot be ascertained, the moment due to a flat spot should be considered; otherwise, the moment due to a general ellipticity should be used. From several measurements, the writer has found that an "out-of-roundness" of 0.25% of the diameter may be anticipated in a circular concrete tank, considering average construction methods. These moments in the wall should be considered in conjunction with the compression in the wall caused by external forces acting on a ring considered circular in shape. These factors give a condition analogous to an eccentrically loaded column.

This treatment of external pressures on walls of circular tanks does not take into consideration the restraint of the bottom, the cantilever effect of the vertical wall segments, or any resistance to torque imposed by the moments due to irregularities, which are of minor importance except in very shallow tanks of large diameters.

GEORGE S. SALTER,[45] M. AM. SOC. C. E. (by letter).—It has often been noted that one of the chief values of a paper is that it brings out some interesting and instructive discussions. Several such discussions were presented on this paper.

Messrs. Silverman, McCormick, Moorman, and Young each brought out clearly, and correctly, that the solution of Equation (10) is nothing new. In this regard the writer wishes to stress the fact that the paper was conceived in the studies made on the design of a particular type of tank—settling tanks for sewage treatment which were 126 ft in diameter with water depth of only 12 to 13 ft. A study of the English literature on the subject gave very meager information on design for tanks of this proportion as, in most cases in the solution of Equation (10), the value of the arbitrary constants *A* and *B* had been assumed as equal to zero. Preliminary studies indicated that such an assumption led to results considerably in error and thus the primary purpose of the studies was to evaluate these constants for the conditions as stated in the paper. It was found that the values of these constants were of considerable importance for tanks in the lower range of values of $\frac{H^2}{r\,t}$. This is indicated clearly in Fig. 2. Since the publication of the paper it has been brought to the writer's attention that apparently a considerable part of the work had been done previously and that various graphs had been presented, chiefly in German publications, some of which are practically the same as some of those given in the paper.

---

[45] Subway Structural Designer, Dept. of Subways and Super Highways, Chicago, Ill.

Mr. Rosengarten suggests the use of pre-stressed rings at the top of the wall in order to simplify the design. This method, and also the method of using a pre-stressed band for the entire height of the wall, were studied; but it was found that they were patented features and also of doubtful savings for the conditions that prevailed.

Messrs. Muckleston, McCormick, Silverman, and Young have stated that the method is not strictly exact in that the value of Poisson's ratio has been neglected. The writer neglected this factor intentionally and made other assumptions as mentioned by Messrs. Muckleston and Young in order to simplify the mathematical work. It was not believed that any of these assumptions were of great importance. The word "exact" was used by the writer in contradistinction to the approximate methods used when the arbitrary constants *A* and *B* were assumed equal to zero. Mr. McCormick goes on to show that for all practical purposes the assumptions made, although not exact, may be justified.

The writer agrees with Professor Moorman that Equation (17) would be understood more clearly if written as he suggests in Equation (30). Equations (32) and (33) are more exact and should be used instead of Equations (18) and (19). Professor Moorman also shows that there is a close agreement between the results secured by the writer's method and that given by W. S. Gray. They should agree as the basis for the two methods appears to be the same.

Mr. Young reveals, clearly, the importance of considering how closely the actual conditions conform to those assumed in the analysis. Probably the most important of these conditions is the restraint at the base of the wall. If the base of the wall is not fixed the values of the moments, shears, and ring tension will be changed materially from those obtained under conditions of fixed base. He also mentions that the analysis may be simplified considerably when the value of θ is greater than π. This simplified analysis has been presented earlier by Smith, Rasmussen, Leeper, and others. The writer, as stated before, was interested primarily in tanks of proportions whose θ-values were close to, or less than, π.

Mr. Dysland's data on estimated savings for the fixed-base tank over the same tank designed for hoop tension only are similar to some studies made by the writer. As the studies made were preparatory to the design of two batteries of sixteen tanks each it will be seen that the total savings would be considerable if Mr. Dysland's data were even approached.

Previous to the plotting of Fig. 3 the writer made up diagrams showing the moment at any height of the wall for the same θ-values as given in Fig. 4. From these diagrams the point of inflection is found readily.

It was not intended to infer that the method could be used for either internal or external loading to any partial height of the wall. The conditions assumed in finding the values of the arbitrary constants state that the moment and shear at height H are zero. This condition obtains only when the loading extends to, or reasonably close to, the top of the wall.

Mr. Mensch states the problem and its answer, correctly, in that American literature contained very little on the subject of design of large-diameter shallow tanks and that the writer's method was developed to design a tank of these particular proportions. A difference of opinion appears to exist as to how much confidence designers will have in such theories. It was hoped that if the method met with the general approval of those who did follow the analysis the method would be of some value in the relatively limited field to which it particularly applies. It might be added that thirty-two tanks, 126 ft in diameter, with a water depth of 12.5 ft, and eight tanks, 75 ft in diameter, and water depth of 14 ft, were so designed and built and are now (1939) in successful operation.

In conclusion the writer wishes to thank all who have added to the value of the paper by their discussions.

ESTABLISHING A SYSTEM OF RECTANGULAR CO-ORDINATES

By Elmer C. Houdlette,[1] Esq.

Synopsis

The story of the Massachusetts Geodetic Survey is that of the matching of two needs with one opportunity. This is not in its generality so very different from the ideal that underlies, in theory, the pattern of all projects to which the Federal Government lent support. Within the province of engineering there are certain special areas of knowledge in which advance has been halted and is awaiting some outside form of impulse. Endowed research may approach them, or a governmental agency, acting in the general interest, may sometimes undertake them; but in the main, they are not employment producing under ordinary conditions.

The Commonwealth of Massachusetts felt that there was a great need for a State-wide local control survey and sought to link it to a confronting human need.

Control surveys are necessary prerequisites to highway planning, Land Court surveys, map-making, flood control, water supply, sewage disposal, and perpetuation of private and public boundaries. They insure the accuracy of measurements incident to such projects, reduce the cost of maintaining the required degree of accuracy and provide means for co-ordinating adjacent projects executed concurrently or at different times.

Faithful use of the fixed points established by the Massachusetts Geodetic Survey will eliminate, for all time, the multiplicity of origins, the over-supply of level datum planes, and the stupendous economic loss of thousands of uncontrolled surveys.

Introduction

The representation of the face of Massachusetts, like the photography and portraiture of the face of Man, has undergone, in the course of the decades, certain easily discernible changes. Due partly to a growing naturalistic sense, partly to improved means of reproduction, it has all been in the direction of a more faithful copy. The story of these changes is one of gradual lifting of that face from its vague and indistinct contours to the more evenly defined surface recognized to-day.

The practice of accurate, up-to-the-minute map-making, courted by, and even indissolubly married to, highways, railroads, regional promotional enterprises, and travel bureaus—as well as sponsored by its traditional guardians, the Federal, State, and local governments—is subordinate to and consequent upon extended travel, broadened communications, and increased land use. As such the demands upon map construction through the years have been conditioned upon the size of those developments and the growth of the science of cartography itself. Its rise has been slow, steady, and rewarding.

---

[1] Associate Civ. Engr., Mass. Dept. of Public Works; Director, Mass. Geodetic Survey, WPA, Boston, Mass.

This is no less true of Massachusetts than of other regions. Thus, in 1829, the necessary preliminary step was taken by the Massachusetts House of Representatives, which then adopted an order appointing a committee "to consider the expediency of determining a map or maps of this Commonwealth as the public exigency requires and report thereon to the next session of the Legislature." Thus, having presumably established the necessity for such a map, the Legislature, on March 1, 1830, passed a resolve directing each city, town, and district to make a plan of its territory on a scale of 100 rods to an inch and to file such plan with the Secretary of the State before June 1, 1830.

Likewise, as a co-ordinating effort in the same direction, on March 30 of the same year, the Legislature directed the Governor to appoint a surveyor to make a skeleton map of the State, the intention being to use this survey as a basis for plotting the information furnished by the various towns. Accordingly, two months later, Robert Treat Paine, of Boston, Mass., was appointed as Chief Engineer, and James Stevens, of Newport, R. I., as an Assistant; Mr. Stevens undertook the triangulation and Mr. Paine the astronomical work necessary to determine the latitude and longitude of many points in the State. Simeon D. Borden, a mechanic employed by the Pocasset Manufacturing Company, of Fall River, Mass., designed and constructed a base-line measuring apparatus. He was persuaded to resign his position and undertake the measurement of a base line in Massachusetts. This line, 39 009.73 ft long, was laid out on the plain west of the Connecticut River in the Towns of Hatfield, Whately, and Deerfield. From it was developed a network of triangulation containing about 550 stations and these data were used to provide an outline map of the State, plotted on a polyconic projection and divided into five sections. In each section a central meridian was determined and from it rectangular co-ordinates were computed.

All town maps were reduced to a common scale and an attempt was made to co-ordinate them, along with the State lines and triangulation points, into a skeleton map that would use all data available at the time. In 1841, the map was completed and engraved in six plates; it was largely a one-man affair in its later stages by virtue of Mr. Borden's own re-surveying and fudging. In the end this map proved to be too thickly garbed with inaccuracies and mis-scalings to serve the increasing demands.

Beginning in 1844, the United States Coast Survey measured a base line along the railroad tangent of the Boston and Providence Railroad, running through the Towns of Attleboro and Mansfield and ending in the southeastern part of Foxboro. Upon this base line (10.75 miles long) there was developed a net of first-order triangulation as part of the general system of the eastern oblique arc, extending from the Epping Base, in Maine, through this Massachusetts Base, and thence to the Fire Island Base, in New York State. The precise stations of the Borden survey were included and adjusted as part of this general plan.

Under Chapter 72 of the Acts of 1884, the Massachusetts Legislature established the Massachusetts Topographical Survey Commission, consisting of three members. This body was delegated to co-operate with the U. S. Coast Survey in completing the necessary control for the preparation of a contour topographical survey and map of the Commonwealth. Later, under the Acts of 1888, Chapter 336, the duties of this Commission were broadened to provide for defining and preserving town boundary lines.

During the period, 1898–1900, the Topographical Survey Commission completed its assignment and published forty-two atlases for as many cities and towns in the eastern part of the State. With this task completed the Commission was dissolved and its duties transferred to the Harbor and Land Commission, which, in an effort to complete the assignment at cheaper cost, combined adjacent towns in one atlas.

By the end of 1912 all the atlases had been published for all the cities and towns east of the Connecticut River. During the period, 1913–1915, the atlases of the section west of the Connecticut River to the New York State line were published.

NEED OF CONTROL

However, in spite of the realization of this long-brewing task, the job, so to speak, was just beginning. Every one was still "in the dark" as to the exact location of a piece of property. True, there were maps showing every city and town in the State; true, by virtue of these maps, progress along the road of charting the State had been furthered; but people were still floundering in uncertainty.

They were still using assessors' maps based upon low standards of control and loose adjustment. The data for such maps had been acquired by closed traverses, supplemented by disconnected traverses, into which were fitted old surveys as described in deeds. These descriptions were rarely confirmed by a map, and no check had been made of the area said to be included by the bounds as given. Many towns still had failed to set the widths of their most important thoroughfares, thus creating a state of confusion for abutting owners who desired to make improvements on their land.

Engineers still were using about twenty-five or thirty different datum planes for level work throughout the State. Suggestive of the diversity that has existed is the variety of the following specimens: Mean low water at Boston Harbor; mean low water at Commonwealth Pier; Boston low-water datum; and mean tide level, Boston City Base, and Metropolitan Water-Works Base. In addition, there are many others.

The economic loss of thousands of uncontrolled transit surveys of all kinds was running into millions of dollars for the State as a whole. Such surveys were based on an unlimited assortment of assumed, magnetic, or true meridians. Plane co-ordinates, if used at all, were referred to an equally unlimited number of origins without regard of their geodetic positions. Levels were based on every conceivable kind of assumed datum plane. It all represented a mass of the wildest confusion.

Value of Control

How much more practicable and scientific, indeed, is a system of uniform and universal measurements used by and serving one and all communities of the State? There is a "hoary-haired truth" that runs to this effect, "You may get out of something what you put into it." This is particularly true of the earth. As the yield of a spring's plowing and sowing, and of a summer's care, protection, and re-plowing, is a fall crop paying triple or more the effort that went into it, so the yield of properly manipulated land control is a saving in money, time, and labor. Not only is this true, but it is also a fact that data gathered from controlled surveys afford a distinct advantage to those who come after.

Engineers are familiar with the advantages of geodetic co-ordination and through them all surveys are made permanent and indestructible, and are incorporated into one uniform system in which every survey is properly placed and related to all others. A controlled survey, being permanently fixed, may be drawn upon at any future time for many other purposes aside from that for which it was originally intended.

The first effort to place elevations in Massachusetts on a mean sea-level datum by means of spirit-leveling, was made under the auspices of the Massachusetts Topographical Commission in 1893. The late C. H. Van Orden, M. Am. Soc. C. E., an officer of the U. S. Coast and Geodetic Survey, was engaged to extend a line of precise levels from Boston, westward across Massachusetts into New York State, to a connection with the precise leveling which had been previously run along the east side of the Hudson River. His data,[2] published in 1894, included a detailed statement concerning instrumental equipment and field methods. In 1923 and 1927, several lines of precise levels were run by the U. S. Coast and Geodetic Survey in Massachusetts and, finally, in 1933, this organization re-ran the Van Orden line from Springfield, Mass., to Albany, N. Y.

In November, 1929, finally persuaded as to the importance of a mean sea-level datum for all surveys, the State Department of Public Works authorized the purchase of a precise level and two invar-faced rods. This marked a major and propitious development in the slow progress that was being made toward the adoption of mean sea-level datum for the Commonwealth as a unit.

Previous to the adoption of the Lambert projection, the increasing use by the Department of Public Works of the twelve Land Court systems of co-ordinates developed a need for simplification. Through conferences and co-operation between the Land Court and the Department of Public Works, on April 1, 1933, geodetic control was established on eight co-ordinate systems, six of which remained as before, while two systems replaced four and two were discontinued. As the need for trunk-line highways passing through many towns and counties increased, the use of eight origins became more or less complicated in that equations of co-ordinates and azimuths had to be applied every time a survey passed from one zone to another. This confusing situation has been clarified and difficulties incident to practical application have been greatly simplified by local control, with ample bench-marks, upon one standard basis.

PROJECTION SYSTEMS

Two methods of projection offer themselves for selection, the choice depending on the geographic figure of the State. A State with a narrow east-west width can be completely shown on a transverse Mercator projection, while another State with a narrow north-south width can be completely shown on a Lambert projection.

In the transverse Mercator projection, standard small circles are selected equi-distant from the meridian of longitude passing through the center of the figure. The development of the plane of projection and the transfer of terrestrial points to the plane is similar to that pursued in the Lambert conformal conic projection, to be described subsequently. Both methods approximately attain preservation of angles at a small sacrifice of accuracy in scale, provided the representation does not go beyond the critical dimension of the projection. The choice of projection depends upon the relative geographic dimensions of the area and the error in scale to be accepted.

Since the maximum error of closure accepted in second-order traverse is 1 : 10 000, it is natural to adopt this criterion as the maximum error in scale acceptable for distances on the projection. Applying this criterion it is found that the ratio will not be exceeded on a Lambert conformal conic projection when the north-south distance of the area to be represented does not exceed 158 miles. Likewise, on a transverse Mercator projection, the east-west dimension must also not exceed 158 miles. As the critical dimension is exceeded, the error in scale increases rapidly. If both dimensions of the area to be mapped exceed the critical dimension then two or more projections will be required to hold the scale ratio to an acceptable limit.

The adoption of either of these methods of projection provides a single system of plane co-ordinates for the entire area. After the geographic co-ordinates of the triangulation stations are converted to plane co-ordinates the computations to determine the position of all intermediate points established by traverse is simplified without any sacrifice in accuracy.

Previous limitations in the form of required use of geodetic formulas and methods, an impracticable expense in many cases, have been eliminated since the formulation of the State plane co-ordinate systems by the U. S. Coast and Geodetic Survey. Any engineer or surveyor in Massachusetts can now utilize the plane co-ordinate system of the Lambert conformal conic projection, and, at the same time, can conduct his work according to the standard methods of ordinary plane surveying.

DIFFICULTIES IN USING SPHERICAL CO-ORDINATES

As is well known the surface of the earth is not a plane but a curved and irregular surface. For purposes of surveying and mapping, however, an ideal surface is assumed which approaches very nearly the shape of the earth if the entire surface were composed of water. This assumed shape is not a sphere, but an ellipsoid of revolution.

Geodetic surveying comprises the extensive work of making observations and computations of positions on the surface of this assumed spheroid. It becomes extremely complicated when the surveys extend over large areas. Also, it requires an intimate knowledge of higher mathematics and astronomy, and the highest degree of precision in the field observations, using the most elaborate and expensive field equipment. All geodetic stations on the earth are expressed in terms of latitude and longitude; that is, each one is referred to a definite place in the network of meridians and parallels that are assumed to cover the surface of the earth in a definite and standardized manner.

It must be perfectly evident that geodetic surveying, although absolutely essential as a basis for precise control, is impracticable for use in ordinary survey work due to the rigorous technique and costly equipment required. Perhaps, for this reason, in spite of the fact that it reached a high stage of perfection and was taught in technical schools many years ago, engineers as a whole have not taken an extensive interest in the general subject, and, consequently, have not developed to the full any standard of practice which might enable them to utilize economically the great inherent possibilities to be found in the existing surveys of the U. S. Coast and Geodetic Survey.

Within these surveys lies a wealth of data, which can be made of tremendous value, not only to engineers and surveyors in every field of activity, but through them to every corporation, commonwealth, county, municipality, property owner, or individual who pays for any kind of instrumental surveying. This value lies in the use of the monumented stations of the national triangulation system as starting and ending points controlling all surveys. Since these points are accurately located on the spheroid, and in relation to one another, they furnish a means of checking the work and of adjusting the errors in the survey. The system of plane co-ordinates permits the use of these stations for control purposes without involving the complicated computations otherwise necessary. In a word, it constitutes a mathematically sound and accurate method of transposing work from geodetic or spherical to plane surveying methods.

The Plane Co-Ordinate System as Adopted for Massachusetts

The Lambert projection adopted for spreading local control stations throughout Massachusetts is based on a geographical frame selected with particular reference to the shape and area of the State. The frame consists of two standard parallels of latitude, held true to scale, and a central meridian of longitude. The north-south dimension of Continental Massachusetts is considerably less than the critical, with consequent reduction of error in scale distances.

In order that the scale ratio applied to distances at the middle of the State shall be equivalent, although of opposite sign, to that for the northern and southern boundaries, it is necessary to select the two standard parallels of latitude at distances from the most northerly and southerly points approximately equal to one-sixth of the north-south dimension of the State. Consequently, the north latitudes of 41° 43′ and 42° 41′ were selected, together with the meridian of west longitude of 71° 30′.

The geographic frame for the insular territory was similarly selected. The standard parallels of 41° 71′ and 41° 29′, together with the meridian of 70° 30′, form the frame. The latter projection excellently illustrates the decrease in scale ratio which accompanies a decrease in the area mapped.

The plane of projection is formed by a cone of revolution intercepting the earth's surface along the two standard parallels of latitude chosen for the frame. The apex of the cone is on the axis of the earth projected through the North Pole into space. The imaginary cone of projection passes beneath the earth's surface in the area between the parallels and above the earth's surface north and south of that area. Approximately two-thirds of the distance between the extreme northerly and southerly continental points in the State lie between the parallels. The remainder is equally divided and lies outside.

Distances between points on the plane between the standard parallels are shorter than those between the same points on the surface, while outside the standard parallels the reverse would hold. Only distances between points along the two standard parallels are true distances and, therefore, equal upon both the plane of projection and upon the surface of the earth. The angles between lines connecting points upon the plane are approximately equal to the angles between the lines connecting the identical points on the earth's surface. This equality of angles is denoted as "conformal."

The U. S. Coast and Geodetic Survey selected the State projection and prepared the plane co-ordinate projection tables to facilitate the computations necessary to transfer a point on the earth's surface, defined by geographic co-ordinates, to an equivalent position on the plane of projection defined by numerical co-ordinates developed on the single State system. The table for changes in latitude gives the numerical value of the radius and Y-co-ordinate on the plane of projection for each minute of change, together with the tabular difference per second for change in the Y-co-ordinate and correction for scale, with their respective logarithmic expressions. The table for changes in longitude gives the change in the divergent angle for each minute. These tables and an acceptable manual of logarithms, expressed to eight decimal places, equip the computer to convert geographic co-ordinates to plane co-ordinates.

The meridian through the origin might be used as the prime meridian, but to reduce the mechanical labor in applying interpolations in logarithmic tables it will facilitate computations to select, in this case, the meridian of west longitude, 71° 30′, just east of the central point of the State, and assign to it the X-co-ordinate value of 600 000 ft, this places the origin on a meridian west of the most westerly limits of the State. Selecting as the other base the parallel of north latitude of 41° 00′ (south of the most southerly point), places the origin of co-ordinates for the single State system at the intersection of these two lines.

History of the Massachusetts Geodetic Survey

The organization entrusted with the task of applying the Lambert conformal conic projection to Massachusetts is known as the Massachusetts Geodetic Survey. Established in November, 1933, as the Massachusetts Local Control Survey, its duty was primarily to make more widely accessible to local engineers the advantages of the Federal triangulation net already laid in the State. In general, its goal was to lessen throughout the State the distances between the marked points in the net by setting down intermediate points. At that time the spacing between marked points, approximately 25 miles apart, giving only $12\frac{1}{2}$ miles from any point to a triangulation point, was too wide for effective local use. The task and expense of running a 12-mile traverse or line of levels to the site of a project were more than burdensome for an engineer undertaking a small job.

The Massachusetts Local Control Survey began its assignment with the running of traverse and lines of levels along highways and railroads from one triangulation station or bench-mark to another, with monuments set at intervals of about two miles en route. The accuracy of the work was to be such as was appropriate to the short length of line and as could reasonably be attained with the instruments available. The error of closure allowed for traverse was 1 : 10 000; and for levels, it was according to the formula:

$$e = 0.4 \sqrt{s} \quad \text{(1)}$$

in which s is the distance, in miles. The plan of operation was as follows:

(1) The U. S. Coast and Geodetic Survey created a unit of its own trained personnel to have administrative and technical jurisdiction over the work.

(2) It appointed an engineer as Director of the work in each State.

(3) Through the State Director, it obtained the loan of surveying instruments, office space, drafting-tables, and other necessary equipment.

(4) The State Director closely supervised the surveying operations to assure economy and efficiency of performance and mathematical accuracy of results, in order that the prescribed standards of the U. S. Coast and Geodetic Survey might be met fully.

(5) The Director established a central office where the results of the field work could be adjusted and computed as the work progressed.

The early period of the project was attended with many of the uncertainties of adjustment and operation, characteristic of the emergency undertakings of the Government since the depression. The first limitation came in less than two months after operations had been begun. With thirty parties in the field in January, 1934, an executive order, reporting the insufficiency of funds to carry on the entire CWA (Civil Works Administration) project, called for a reduction of the personnel from 375 to 75 workers, by February 15. Accordingly, the field equipment was collected preparatory to tying up the project altogether.

Up to this time the office work consisted chiefly in computing and plotting on the Lambert projection the co-ordinates of the corners and mid-points of the fifty-four topographical sheets of the State for the Massachusetts Land Court. However, on February 23, efforts to have the project personnel approved for 182 employees were successful. Fourteen field parties and forty-one office men were re-hired forthwith; but in spite of this reinforcement the force was still insufficient to continue the traverse work west of the Connecticut River. This plan, for the time being at least, had to be abandoned.

The next major adjustment came on April 4, 1934, when the project was transferred to the ERA (Emergency Relief Administration), whose original approval of 177 workers was increased by August to 230. This provided twenty-one field parties. An order of September 24, 1934, reducing all salaries to a common basis of $16.80 per week, from Supervisor to Rodman, was rescinded within a week.

The first few months of this re-adjustment brought along anxiety and disturbing jolts. The accompanying loss in personnel definitely tended to obstruct the program. However, the spirit was unflagging and certain accomplishments stood out from the condition of disruption as indicated by the report for the year ending December 31, 1934:

(1) The project had completed 585 miles of traverse, including 1 170 monumented stations; and 343 miles of preliminary computations showed an error of approximately 1 : 18 400.

(2) The project had completed 304 miles of first and second-order levels, including the establishment of 679 bench-marks.

Meanwhile, by virtue of the triangulation and projection work, the demand for added service was increasing. One valuable use pointed in the direction of improved forest fire control. It happened that up to this time the "tying-in" of fire towers with triangulation was not complete. The Department of Conservation in the fall of 1934 requested the Survey to complete the "tying-in" process; likewise, in order that the Lambert projection might be used on the topographical sheets for the location of forest fires, it desired that the Lambert co-ordinates be computed for all the fire towers in the State. At about the same time the Massachusetts Land Court requested a computation of the Lambert co-ordinates for all the triangulation stations on Martha's Vineyard and Nantucket, as the triangulation stations on these two islands had been adjusted on the 1927 North American datum.

At the beginning of this project, the geographic positions of all the established triangulation stations in the State, with the exception of the seventeen precise stations, were based on the North American datum. Until such time as the remaining triangulation stations were either re-computed or re-adjusted on the 1927 North American datum it was necessary, for preliminary traverse computations, to apply to each triangulation station as it was used, a correction to the published position to place it upon this datum. The rapid determination of the amount of correction to be applied to a given point was facilitated by the construction of a correction chart based upon the seventeen precise stations furnished by the U. S. Coast and Geodetic Survey.

These stations were plotted in correct position on an accurate map of the State and the amounts of the differences in latitude and longitude between the North American datum and the 1927 North American datum were noted. These points were connected by direction lines which were divided into equivalent parts representing the units of difference in latitude between the stations. These subdivisions established points of equal correction which could be connected to equivalent points on adjacent direction lines. The space between the connecting lines defined an area within which all stations were to receive equivalent correction in latitude. The distribution of the corrections in longitude were similarly determined.

Thus, the map of the State was covered with a somewhat rectangular and more or less regular grid, the unit subdivisions being about a mile apart in the east and west direction and somewhat less north and south, corresponding to connections to the nearest 0.001 sec in longitude and latitude. This map became a chart showing the amount of correction to be applied to the geographical co-ordinates of points included between the parallels.

Plotting the position of a point (defined by geographical co-ordinates on the North American datum) places it in one of the numerous grid areas. Thus, the corresponding amount of correction is determined and the position of the point is adjusted to the 1927 North American datum.

This chart was found, by later triangulation, to give results in general only to the nearest foot, but it served the purpose of determining a preliminary adjustment of all the traverses and showed whether the work had been completed in accordance with the specifications of second-order accuracy. Its main purpose, however, was to give a quick solution of control points in order that this information might be available to the United States Geological Survey in re-mapping the State.

In 1935 the equipment and personnel of the project were strengthened to the extent that the original program could be more fully and thoroughly completed and new work could be handled in its course. In January, the quota of employees was increased to 300, including 26 field parties.

A further increase in personnel to a total of 367 was made upon the transfer on November 1, 1935, of this project from ERA to WPA (Works Progress Administration) control. However, the accompanying shortening of working time from 35 to 24 hr per week brought about a decided slowing down of the work which was ever increasing in volume. Prior to January, 1936, transits and levels used in all field work were loans to the organization, and, in general, they were only in fair condition. As the transits read merely to the nearest minute, about 15% of the traverses had to be rejected. In time, this state of affairs was brought to the attention of the local officials who obligingly agreed to the purchase on a rental basis, of twenty-four new 20″ and 30″ transits. With this improvement, errors of closure approached that of first-order accuracy and rejections were reduced to about 5 per cent.

Additional undertakings by the Survey call for special mention. During 1935 it started preparing maps for each city and town in the Commonwealth, showing the location of all traverse and triangulation stations and bench-marks, such maps to be used by the localities for local control surveys within their limits. In October, the project was requested by the Department of Public Health and the various municipal water supplies to establish bench-marks, determine the heights of high and low water, the crest of dams and spillways, and establish the elevation of stand-pipes and of the ground-water level in driven wells on a common mean sea level basis. Such a unified survey makes it possible to judge whether there is a presumption that a given city or town might find it physically feasible to obtain additional water from a neighboring source.

All systematic and reliable information about relative levels is certain to help in planning. It will be of potential assistance in times of emergency, which can partly be foreseen as to type but which can never be foreseen as to time or detail. There is a natural community of interest between adjoining towns and cities because of the reciprocal assistance they might afford each other in times of need, when one had been better able than the other to cope with drought conditions. Less spectacular is the opportunity for temporary tie-in with a neighboring supply in the event of temporary breaks or of breakdown of the servicing. A more glaring illustration is the assistance that sometimes can be rendered by a neighboring community in the event of large or protracted fire, or of suddenly threatening depletion of the ordinarily sufficient reserve because of fire.

During the same year (1935) requests for control were received from sixteen cities and towns around Boston. An additional request was received for a large amount of control for military purposes within the area of the newly established National Guard Camp at Bourne on Cape Cod. One encouraging feature about these requests was the marked inclination toward the adoption of the State co-ordinate system. By the end of that year 1 618 miles of first and second-order levels had been adjusted and 1 275 miles of traverse completed in the field with an average of error of closure of 1 : 23 100.

The supreme test of the strength and resources of the organization and of the fortitude of its engineers presented itself in March, 1936, when large areas of the State were engulfed by unprecedented conditions of flood. The Massachusetts Geodetic Survey was called upon to accept a task never before undertaken, namely, the collection, by specially directed and equipped eye-witnesses, of authentic high-water data. A plan to establish a systematic series of bench-marks at bridges and dams along the principal rivers in the State already had been partly executed. Thus, with a trained organization and a substantial vertical control base achieved, all was in readiness to launch the flood survey; and on March 18, supervisors were instructed to notify all party chiefs to prepare their men for quick action in the field, if and when the emergency arose.

The men were to reach the flooded area over as many roads as possible, in order to place the high-water marks at well distributed points along the entire course of streams where flooded conditions prevailed. An order was issued on March 19, and the full personnel of about 200 field men were thus assigned to placing suitable marks, recording high water at the site and at the very time it occurred. This work continued until the extreme flood stage had passed. As rapidly as the field reports were received at the Boston Office, the position of each mark was plotted on the town maps and these reports were grouped and dispatched to the several field supervisors for allotment to especially organized level parties.

During the fall of 1936, the U. S. Coast and Geodetic Survey asked the State Survey to determine the magnetic declination at about seventy stations scattered over the State, from the tip of Cape Cod to the New York State line, including all the islands. The results of 24-hr observations made at Mt. Wachusett for seven consecutive days, to determine diurnal variation, were compared with the observations at the Observatory in Cheltenham, Md.

In the beginning of 1937, also by request of the U. S. Coast and Geodetic Survey, two first-order arcs of triangulation across Massachusetts were started, together with the necessary second-order triangulation, to tie in all the completed traverses, in order that a final adjustment might be made on the 1927 North American datum.

An idea of the amount of Survey work accomplished may be gained from the following summary, through September, 1938:

Traverse:	
Extent, in miles	2 605
Number of stations established	4 700
Number of stations with preliminary co-ordinates	3 427
Number of stations with final co-ordinates	1 272
Average error of closure	1 : 35 400
Triangulation:	
Number of stations established	550
Number of first-order adjusted stations	55
Number of second-order adjusted stations	223
Bench-Marks:	
Extent of first-order levels, in miles	1 320
Extent of second-order levels, in miles	3 760
Number of first-order bench-marks	1 850
Number of second-order bench-marks	8 101
Magnetic Stations:	
Number of stations established and adjusted	68
City and Town Maps:	
Number of maps completed	385

Publication Program

One interesting feature of the Survey's work was the opportunity of printing its records, investigations, and standards. In June, 1935, the first publication of the Survey entitled "Leveling in Massachusetts" was issued. This volume contained the descriptions and elevations of all bench-marks, including those established by the U. S. Coast and Geodetic Survey and by the State project, together with a history of leveling in Massachusetts, specifications for first and second-order leveling, a discussion of the various datum planes, and a chart showing the relation of some of the principal datums in use and their relation to mean sea level.

Fortunately, the Traffic Survey was in the same building as the Survey. As its work was about to be terminated in August, the Geodetic Survey fell heir to a complete plant with all its divisions, including reproduction equipment, modern multilith and mimeograph machines, photostatic and reproducing cameras, dark room, and plate-making equipment.

Immediately the publication of a second volume entitled "Computations of Spherical and Grid Coordinates with Tables" was undertaken. This book contained instructions for solving geodetic positions, a description of the Lambert projection, and directions for computing co-ordinates, together with tables.

During the year, a request was received from the U. S. Geological Survey to undertake as part of the survey work in this State, the determination of the elevations above mean sea level datum, of the reference marks at the forty-two stream-gaging stations. In 1937, a report was issued entitled "Stream Gaging Stations in Massachusetts." This report contained notes on equipment and operation of stream-gaging stations, and stream-flow data as compiled by the U. S. Geological Survey, together with the descriptions and elevations of the reference marks at each of the forty-two stations.

Information gathered out of the flood-control activities formed one of several very significant books published by the project during 1936, "High Water Data: Flood of March 1936." This is a tome of about 350 pages, based upon about 1 400 observed points which required about 800 miles of levels to determine the elevations.

An April, 1936, release by the project was a 46-page, very readable book, entitled "Status of Land Surveying in Eastern Massachusetts." Another volume, "Technical Procedure for Geodetic Surveys," released the following month offered a manual of instruction in instrument operation, methods of procedure, and recording of data necessary for standard triangulation, traverse and leveling survey work. This publication has proved of immense value in standardizing survey work in the State. A year later a volume was published entitled, "Plane Coordinates of Minute Intersections of Meridians and Parallels of Latitude Based on the Massachusetts State System."

The various volumes mimeographed by the Reproduction Section testify to painstaking work on the part of the publishing unit of the project. The demand for these publications was more than flattering, especially in view of the lack of any provision for advertising or book promotion campaigns.

THE USEFULNESS OF THE PLANE CO-ORDINATE SYSTEM

What is the procedure of a surveyor who undertakes to make use of the plane co-ordinate system as devised for Massachusetts? He will have previously obtained from the agency the plane co-ordinates of the monuments at which he proposes to begin and to end his survey, and also the plane bearings or the plane azimuths, from these monuments to their respective azimuth marks. Then, setting up over the first monument with the vernier at zero, he sights to its azimuth mark. From this line of sight he turns the angle and measures the distance to the next point in his survey which the instrument is to occupy. He also computes the plane bearing of this line from the given plane bearing between monument and azimuth mark. He carries his calculated plane bearings, in the usual manner, right on to the end of the survey at the terminating monument, and on through the monument to its azimuth mark. Instantly, he has a check on all the instrument work, for the calculated bearing from monument to azimuth mark should be the same as that which was furnished by the agency.

After distributing his angular error, he computes the plane co-ordinates (latitudes and departures) of his survey, starting with those furnished him for the beginning monument. His co-ordinates for the terminating monument should agree with those previously furnished him. Thus, he not only has a check on both instrument work and chaining, but he has made a controlled survey which is permanent, and is also in its proper position with respect to all other surveys in the system so that it can be used in the future for many other purposes. Of course, he should correct the co-ordinates for his survey by distributing his error of closure in latitudes and departures.

If he prefers to use azimuths instead of computed bearings, he first sets the vernier to read the given azimuth from the beginning monument to its azimuth mark and sights to that mark. Thereafter, instead of measuring the subsequent angles, he simply reads the azimuths of the various lines directly from the vernier plate and closes on the previously given azimuth at the terminating monument. Because the magnetic bearings will vary from corresponding plane ones (often considerably), in various parts of the State, the magnetic bearings of all lines, and the date of the survey, should be recorded.

The surveyor finds not only that the system can be used without difficulty but also that it simplifies the use of control data and gives a permanent general grid for the entire State. County boundaries, township boundaries, property boundaries, intersections of roads and streets, and any prominent features of a region can be located accurately with definite X and Y-co-ordinates. These plane co-ordinates can be readily transformed into latitude and longitude, and the point can thus be definitely located in the network of meridians and parallels that serve to locate points in the earth's surface. If, in some manner, the marker at such a point should be destroyed, it could be relocated definitely on the ground from its relation to other marked points. This is an important characteristic and one that should be given due consideration by all engineers and surveyors.

There have been strong objections to the use of grid co-ordinates based on the State system because of the large numbers involved. These large numbers were used in the State system only to avoid minus values in co-ordinates in any part of the State. In other words, the origin of the projection $X = 0$ and $Y = 0$ might be said to be an arbitrary point. Therefore, if the relation of the grid azimuth were maintained, one might use any set of X and Y-values.

The minimum requirements to compute an existing traverse, or tie it into the State system, are the grid co-ordinates of one marked station and grid azimuth from that marked station to another station visible from it. The co-ordinates are usually in hundred thousands, such as $X = 315\,718.63$ and $Y = 457\,245.08$, shown in Fig. 1. If the computer objects to carrying such large numbers in his computations, a value such as $X = 0$ and $Y = 0$ may be substituted for the known co-ordinate values of the marked starting station. In general practice, however, it is customary to assume some number sufficiently large so there will be no minus values such as 10 000 or 50 000. After computing the values of the traverse, the difference between the original co-ordinates and the starting co-ordinates should be added to the computed co-ordinates. This has been done in Fig. 1. The computations using natural lines and curves, designated by **S** and **C**, will be self-evident.

Co-Ordinates by Special Tables

A table of plane co-ordinates of minute intersections of meridians and parallels of latitude was prepared to enable engineers to compute the co-ordinates of any geographic position by interpolating rather than using the longer direct method involving 10-place natural or logarithmic tables. While especially valuable for plotting purposes, the accuracy obtained in most cases will be sufficient for any survey, giving results checking within 0.01 ft.

The basic values for the projection in Massachusetts are the radius, in feet, from the origin of the cone of the projection, of parallels of latitude, and the value known as *Y*, in feet, of the length along the central meridian, of the intercepts between minute parallels of latitude. The value, in seconds, of θ, the angle at the origin of the cone between the central meridian and any other meridian, is also given.

FIG. 1

Using these basic values, the co-ordinate values of the intersection of every minute of latitude and longitude, within the State boundaries, were computed. This necessitated approximately 25 000 separate computations for the *X* and *Y*-co-ordinates of these minute intersections. These computations were somewhat simplified by the fact that they were started at the 71° 30′ meridian, known in the projection system as the prime meridian, which has an *X*-value of 600 000. Thus, for about 100′ east and west of the prime meridian, the computed distances from this point were added to or subtracted from 600 000—added when east of the prime meridian and subtracted when west.

FIG. 2

When all the co-ordinate values for the minute intersections were computed, they were arranged in a tabular form of which Fig. 2 is a sample. A range of 15′ of latitude forms the side argument and 3′ of longitude forms the top argument. Each vertical column of 1′ of longitude is divided into four sections.

Section 1 gives the value of the co-ordinate, X, and between adjacent values, their increments, $\Delta' X$. Section 2 lists the difference, ΔX, in the value of X between each minute of longitude progressing easterly along a given parallel; and between these ΔX-values the differences, $\Delta_2 X$, of ΔX between successive minutes of latitude along a given meridian progressing northerly. Sections 3 and 4 are identical with Sections 1 and 2, except that the values listed are for the Y-co-ordinates. Thus, at a given latitude and longitude straight line differences can be found to the next larger minute of latitude and longitude. The complete table thus formed for the State of Massachusetts consisted of approximately 270 pages similar to Fig. 2, giving X and Y-values and their increments.

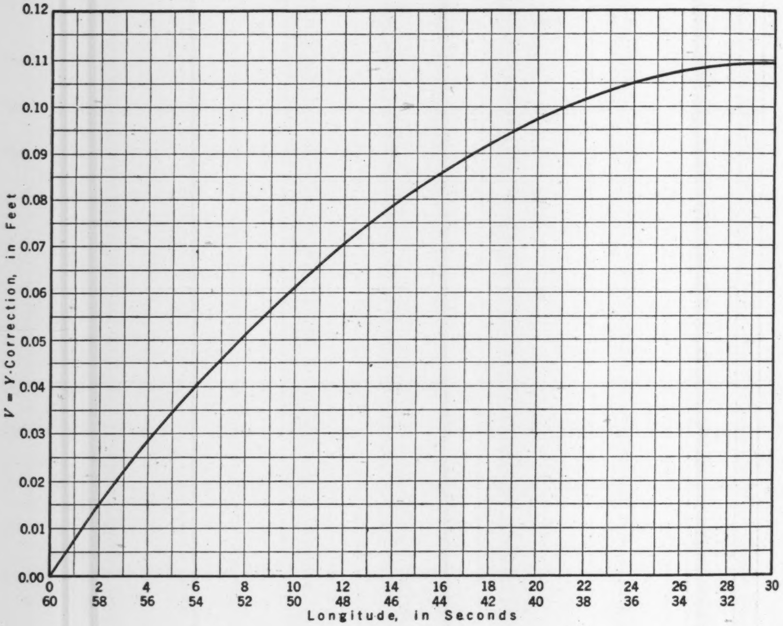

FIG. 3

To convert to grid co-ordinates a given latitude and longitude listed to hundredths or thousandths of a second, it is only necessary to locate the required page in the table similar to Fig. 2, by use of a tabulated key, which gives the X and Y-values of the intersection of the given latitude and longitude, rounded off to the next lower full minute. Then, by multiplying the seconds, divided by 60, into the Δ-values and their increments found in the tables, a straight line interpolation can be made.

The *Y*-co-ordinates, as determined from the tables, are slightly in error because, between minute intersections, the parallels of latitude are assumed to be straight lines and actually they are curved. A graph was constructed (Fig. 3) giving corrections to compensate for this discrepancy. The values of *X* and *Y* as determined from the tables and the *Y*-correction are within 0.01 ft of those obtained through the use of the regular computation, using logarithms for changing geodetic positions to grid co-ordinates. Also, by the use of these tables, the time required to compute a grid co-ordinate is shortened by 65 to 75 per cent.

Y = 283,115.88

FIG. 4

If the intersection tables are used to obtain the co-ordinates when a geodetic position is given for the starting station, the other computations in a traverse need only 7-place logarithms or 7-place natural function tables, which is the same as required if the traverse were based on local co-ordinates. The only difference in computing traverse on the State system and on a local system is the starting azimuth. On the State system a simple computation, called a

FIG. 5

grid inverse, will give the azimuth and distance between two known stations. Using this inverse azimuth the work may proceed as with any other traverse.

A sample computation using the table of minute intersections (Fig. 2) and the graphic correction (Fig. 3) is given in Fig. 4. The chosen station, Sommint, is located so as to be covered by the sample page illustrated in Fig. 2. It is believed that the numerical work will be self-evident.

To check the results in Fig. 4, a computation of the co-ordinates for the same station by solution of the formula is given in Fig. 5, on the standard form of the Massachusetts survey. The detailed procedure needs no special comment. In particular, the close check with Fig. 3 is to be noted.

CONCLUSION

The value to all future land surveys of the rectangular system of plane coordinates will be in proportion to the local and community use made of Massachusetts Geodetic Survey work already completed and to be accomplished. Every effort is being advanced to provide each community in the State with fixed points of horizontal control together with the elevations above mean sea level.

Such stations are being located on individual town maps prepared for ready reference. Suitable symbols to identify the points are listed and explained in an accompanying legend. At each of these horizontal control stations the following data will be available: (1) A description of the general location; (2) a diagram showing distances and directions to station reference points; (3) plane co-ordinates on the State system; (4) direction angles, distances, and azimuths to adjacent stations; and (5) elevation above mean sea level.

Faithful use of this information will eliminate for all time multiplicity of origins, the over-supply of level datum planes, and the varied waste of land surveys, and will contribute to an enlarged network of fixed points whose permanence of location will rival that of the sun. It remains for the towns and small communities themselves to effect this realization. It remains for them to see to it that future public or private surveys are tied to and developed upon the data available at control stations; that the positions of all important points and of monuments are made permanently recoverable; that old established points are co-ordinated with the new control points and proper recomputations made; and that all future local work is tied to the State system. It likewise remains for these communities to appropriate sufficient funds to carry on this local work and to maintain complete records of procedure and results for future use.

Such is the story of the establishment of the system of rectangular coordinates in the State of Massachusetts and such is the path that must be followed for its complete extension and realization.

THE LAND COURT AND ITS ENGINEERING PROCEDURE

By Clarence B. Humphrey,[3] Esq.

Synopsis

The purpose of this paper is to place before the engineer the work done by the Land Court; to acquaint him with its practice and procedure; to provide a background for his examination of title deeds; and to encourage the use of the Massachusetts Geodetic Survey triangulation points and traverse stations in connection with the State-wide co-ordinate system.

It is hoped that engineers connected with State and town governmental agencies in Massachusetts, knowing the present situation in regard to independent surveys, will co-operate and place their survey projects on this system, thus making available valuable map data.

From its beginning the business of the Court has increased at a uniform rate, falling off slightly during the depression period. The number of registration petitions filed is about 18 000 and certificates issued about 150 000. The decree and subdivision plans on file number about 25 000 and the assessed value of land registered is about $200 000 000.

Early Grants

The original source of title to the soil in New England, as in other parts of the United States, was in the English Crown which claimed it by the right of discovery and possession. The King was the owner and thus all titles to landed property were derived from a grant of the English Crown.

First, there the Royal Grants, among which might be mentioned the Plymouth Company in 1606; the Massachusetts Bay Company in 1629; the Ferdinando Gorges grant in 1639, covering most of Maine; the River Towns, in Connecticut, in 1662; the Province of New Hampshire in 1679; and the Narragansett Bay settlement under Roger Williams in 1643. In 1691 the Massachusetts Bay Colony received a new charter, and its jurisdiction covered what is now Maine and Massachusetts. The Plymouth settlement was included in the Massachusetts Bay Province thus reconstructed.

Next came the Colonial Grants with the power vested in the General Court. These grants were to individuals and groups of individuals who became known as proprietors. The grants to individuals were not numerous and seldom contained more than 350 acres, while the grants to the proprietors for laying out of plantations would contain a tract about 6 miles square. These plantation lands were surveyed and divided; and at legally called proprietors' meetings, selections of the divided parcels were made by drawing lots. Although these deeds were properly recorded the title itself runs direct from the proprietors' records.

---

RECORDING

Under the Massachusetts recording system [4] in vogue since 1634, the document recorded is a deed, which is operative without record, the title passing upon the delivery of the deed and before it is recorded.

According to the General Laws:[5]

> "A conveyance of an estate in fee simple, fee tail or for life, or a lease for more than seven years from the making thereof, shall not be valid as against any person, except the grantor or lessor, his heirs and devisees and persons having actual notice of it, unless it is recorded in the Registry of Deeds for the county or district in which the land to which it relates lies."

This Section although revised many times still reads very close to the original ordinance of 1640. The next paragraph, Section 5,[5] provides that:

> "The record of a deed, lease, power of attorney or other instrument, duly acknowledged or proved as provided in this chapter, and purporting to affect the title to land, shall be conclusive evidence of the delivery of such instrument, in favor of purchases for value without notice claiming thereunder."

These two Sections (Sections 4 and 5) are the very basis of the recording system, which not only preserves the evidence but gives a legal priority to the grantee of the recorded deed, insures a safe depository by the county, and makes it possible to investigate the title to property. First used in the Plymouth Colony in 1634, it remained in vogue until 1898 when it was modified by the adoption of the Land Registration Act.[6] The system proved well suited to the needs of the people and in a greater part of the Commonwealth it still would be satisfactory. However, with the passing of time, as cities became congested, as the records became exceedingly complicated, and as the methods of dealing with land have changed, real estate operators found it advisable to have their titles in such shape that they could be transferred speedily, the same as shares of stock, or other securities. For such purposes the existing system was not adequate. In the cities there was too much record title and in the country there was, at times, too little. Numerous other evils of the system needed correction.

Title to land is acquired in various ways, such as by inheritance, by will, by mortgage, and by direct purchase. During these changes over a period of years many things might occur to invalidate a title. Thus, no prudent man will purchase land until he has had the title studied by a competent examiner, as title on which money is loaned, or on which the issue of bonds is based, must be valid. If the land has repeatedly changed hands, it will be found that the title has been examined and re-examined by many separate interests with the resulting duplication of expense; and even then, the most exacting scrutiny might fail to disclose vital defects, such as prescriptive rights.

[4] "The Origin of the System of Recording Deeds in America," by Joseph H. Beale, Jr. Harvard Univ., 1907.

[5] General Laws, Tercentenary Edition, Chapter 183, Section 4.

[6] "Land Registration Act of Massachusetts," by Charles Thornton Davis, Judge of Land Court. (Read before the New York State Bar Assoc., 1908.)

It was said by the Hon. Fred E. Crawford,[7] of the Boston Bar, that "if a new beginning could be made" back of which it would be unnecessary to go—and if a title could be given new life and started on a new career—much would be accomplished. In theory, all titles come from the State and if a title might be considered as coming anew from the State, then from that day the State would stand behind the title. This is what the Land Court does.

To Australia—the home of that other great principle, the Australian ballot --goes the credit for breaking the precedent in passing title to land. Sir Richard Torrens was at one time Commissioner of Customs in South Australia. Apparently annoyed at the delay in transfer of titles in land, due to the time consumed in the examination and re-examination of back titles, he devised a system of registration of title to land incorporated in what became known as "The Torrens Act."[8] This furnished the idea for legislation adopted in various parts of the United States.

The first American State to adopt some system of conveyancing by the registration of titles, was Illinois in 1895; then came Ohio in 1896; California in 1897; and Massachusetts in 1898. Since then Acts have been adopted in some form or other by Colorado, Minnesota, New York, North Carolina, Oregon, Washington, Utah, Virginia, North Dakota, South Dakota, and Georgia; also Hawaii and the Philippine Islands. The Act adopted by Massachusetts was distinctly local—drawn to fit existing conditions and establishing a system designed to give relief from the defects of the old method.

THE LAND COURT

In the Commonwealth of Massachusetts there are fourteen separate and distinct counties and twenty-one Registries of Deeds. The Massachusetts Act (now the General Laws, Tercentenary Edition, Chapter 185)[5] provides for a separate body, called the Land Court,[9] having State-wide jurisdiction, with a judge, two associate judges, and a recorder. This new system was grafted on to the existing recording system by creating a Land Registration Section in each Registry of Deeds, and making each Register an Assistant Recorder of the Court, *ex officio*.

The Court is situated in Boston, Mass., and its decrees are sent out for recording to the Assistant Recorders. On the authority of these decrees certificates are issued and all subsequent transfers are made by certificate. Thus, the title is given a new lease of life and a day is set, after which an examination is unnecessary. The Act not only provides machinery whereby ownership of the premises is adjudicated, but boundary lines on the earth's surface are judicially determined, and remain definite and fixed. To register a title the procedure is as follows:

(1) The petitioner files a petition and a plan with the recorder and pays the statutory fee. The petition describes the land as claimed; states all known encumbrances and adverse claimants with their addresses, whether admitted or

[9] "The Land Court: Being a Copy of the Land Registration Act, Chapter 185, General Laws (Tercentenary Edition) with Procedure and Practise," 1936.

denied; and gives the names and addresses of all adjoining owners. It is accompanied by an assessor's certificate signed by the local assessor verifying the adjoining owners as they appeared at the last assessment for municipal taxation. The plan is made from an actual ground survey and shows the land claimed with the location of the boundary lines. The petition is given a number, the first one filed being No. 1, and these numbers run consecutively throughout the State. All papers with the petition, as well as the plan itself, bear this same case number. At the same time, a notice of the action is filed in the registry of deeds.

(2) The petition is referred to a Court examiner to report on the state of the title; he is allowed two weeks for this work. He must be an attorney-at-law, appointed by the Court. When his report is filed, notice is given to all parties in interest by publication once each week for three successive weeks in a newspaper in the county where the land lies. It is expressly provided that by the description in the notice "to all whom it may concern," all the world are made parties defendant and are to be included by default, and that the registration proceeding is *in rem suam*. The return day of the notice must not be less than twenty nor more than sixty days from the date of issue, and within seven days the recorder sends an attested copy of the notice to each person named therein, by registered mail. An attested copy of the notice is also posted on the land itself by a deputy sheriff, not less than fourteen days before the return day. Such other and further notices are given as the Court may order.

(3) If on or before the return day no one appears to object to the registration of the title to the land in the name of the petitioner, the examiner's opinion with the complete abstract of the record title is carefully read and considered by the Judges. Even if no objections have been made, further service, or additional information, or both, are many times required. After all these precautions have been taken, an order for decree of confirmation and registration of the title is entered in the name of the petitioner.

(4) If on the return day appearances and answers have been filed objecting in part or in whole to the petitioner's claim for registration, then, on motion, the matters involved are set down for a formal hearing before the Court. If the objections are not disposed of in Court—by agreement, by stipulation, or by withdrawals—the case is heard and a decision filed by the Judge. This decision is final upon all questions of fact, but any questions of law arising in the Land Court may be taken directly to the Supreme Judicial Court within twenty days after the decision is filed. When remanded to the Land Court an order for decree is entered as in an uncontested case.

COST OF REGISTRATION

Upon filing a petition, the petitioner is required to deposit $25 plus one-tenth of 1% ($1 per $1 000) of the last assessment for taxation; and when the decree is issued he pays the further sum of $2 for the decree and copy, and one-fourth of 1% of the assessed valuation, but not less than $10, nor more than $1 000. At the same time, the recorder's office collects $5, which is transmitted to the registry with the decree, to pay for entering the papers and for preparing the certificate and owner's duplicate. In addition to these statutory charges, the petitioner pays his title examiner and also his engineer for survey work and plan. The $25 is for publication, sheriff's fees, etc., and if any surplus remains when the case is closed, it is returned to the petitioner. If such deposit is not sufficient, then the remainder is paid upon the request of the recorder and before any decree issues.

The one-tenth of 1% is paid as an assurance fund to be deposited with the State Treasurer who keeps it invested and adds the income to the principal; and when the fund amounts to $200 000, as it did in 1929, the income is used to help defray the expense of the Court. This fund is for the purpose of reimbursing the Commonwealth for any sum its Treasurer may be called upon to pay out because of negligence on the part of any officer under the Land Registration Act. The man given a title under a decree of the Court obtains an indefeasible title, one that is settled and that remains settled. This is most important.

SURVEYS AND PLAN WORK

The Land Registration Act does not provide for an engineer, but Judge Charles Thornton Davis, who has been with the Court from 1898 to 1936, early recognized the necessity for an engineering department. He established it as an adjunct to the Recorder's Department.[6]

Instructions as to surveys were issued to acquaint the engineers with the requirements of the Court in regard to surveys and plans, and to standardize Land Court surveys. This was necessary in order to obtain in the first instance full engineering data, showing field monuments, which would enable any engineer to reproduce the lines upon the ground. In the past the fault has been that plans filed in the local registries lacked both monuments and survey data and, at times, even distances on the property lines themselves. Plans showing property and subdivisions are still recorded which have little or no value because the lines shown on them are in dispute and the engineer who made them has long since been dead. It is a case in which the engineer considered the missing data as a part of his stock in trade. This condition, however, should not discourage the filing of such plans, because some deeds are so ambiguous that even a sketch of the land sought to be described would be of assistance.

What is a survey? What are the requirements for a model plan and what data should be shown thereon? To be of any value, a plan should show plotted lines drawn to scale, distances, angles or bearings, survey notes when necessary, and the character of existing physical boundaries and monuments. Thus, all lines may be reproduced accurately by another engineer many years hence should occasion require.

In making plans for the Land Court:

(1) The plan must be made on tracing cloth.

(2) The sheet may be 18 in. by 24 in., or 24 in. by 36 in., or any convenient larger size.

(3) The title must state the location, scale, date, name, and address of the surveyor.

(4) The plan must show the north point, town, or county lines, names of adjoining owners, passageways, street lines, boundary monuments, all fences,

walls, buildings on or adjacent to lines claimed (using proper conventional signs), and all other natural monuments pertinent to the purpose.

(5) The scale must be such as to show clearly all data necessary.

(6) The area may be by calculation or by scale; if by scale the sign, ±, is affixed.

(7) Such parts of buildings and other physical features on adjoining land as are within 10 ft of boundary lines are shown.

(8) Boundaries of the property, pertinent dimensions, and all physical features are shown in black; all traverse and surveying data in red.

(9) The plan must indicate plainly how each corner, property line, and reference point is marked on the ground. This information is essential, for the reason that respondents often object to a plan and survey because a stone bound, partition wall, retaining wall, or other object used to mark a boundary, has been erroneously included or excluded. On this account careful inquiry should be made to determine the ownership of such boundary monuments. If necessary a note is included describing what part of the boundary monument is used.

(10) The parcel sought to be registered must be enclosed within blue tinting.

(11) The plan should be oriented so that the top is in a general northerly direction.

Engineers are always reminded that the land may be bounded on ways, that is, streets, avenues, highways, boulevards, and parkways, also on railroad locations and public lands. Such ways are monuments, possibly referred to in the title deeds and as such the data are, or should be, deposited in the various public offices and the county registries. They are asked to examine these data and to place on the plan the initial data points used in making the survey.

In regard to bearings, engineers are asked to carry forward, if possible, one bearing used in a previous registration case; if not, to use a bearing found on an official street plan; or, as a last resort, to read the magnetic bearing of some one line of the new survey. All bearings on the survey must be relative, computed from measured angles.

A computation sheet is required, showing traverse on the lines claimed, or on lines from which the lines claimed are located. It gives computed latitude and departures and additional data, if necessary and not shown upon the plan, so that rectangular co-ordinates of all points on the plan can be computed.

On the plan is the endorsement: "I certify that this survey was made in accordance with Land Court instructions," with the surveyor's signature. Thus, the engineer must have all these requirements in mind when making his survey.

This plan is indexed and casually examined; if any data are missing or monuments should be set, the attorney of record is so notified. This procedure expedites matters when the case is ready for decree, which may be months later depending on the questions involved. The plan is used throughout the hearings. Usually, no changes are made; in some cases the lines are changed by agreements; and in still other cases, due to protracted hearings and formal decisions, many changes are made. When, however, an order for final decree is issued a plan called the decree plan is prepared in the Engineering Department. These plans are all of one uniform size, 10 in. by 15½ in.

This decree plan is sufficient in itself, with all survey data and monuments shown on it, to enable the established lines to be found on the ground. From this plan the decree is drafted describing the land as registered and setting forth all encumbrances, easements, or appurtenant rights, as set out in the order for decree. The Court early decided to use a bounding description rather than a so-called running description and, by the plan reference, to make the plan itself a part of the decree of the Court. The Supreme Court has often held that, by a well settled rule of construction where a plan is referred to in a deed, the lines, courses, distances, references to monuments, and other particulars appearing on the plan, are to be regarded as much as they would be if expressly recited in the deed.

The descriptions in the decrees, therefore, are brief, using a general bounding description, grouping together shorter lines running in the same general direction, but reciting, however, the adjacent owners and natural boundaries. The first boundary is usually a highway; thence the description reads clockwise. The plan reference most often used is as follows:

"All of said boundaries are determined by the Court to be located as shown upon plan numbered * * *, which will be filed with the original Certificate of Title issued on this decree, the same being compiled from a plan drawn by John Doe, Engineer, dated * * *, and additional data on file in the Land Registration Office, all as modified and approved by the Court."

The decree and plan are sent to the assistant recorder for the district within which the land is situated. He transcribes this decree in a registration book and this entry is the original certificate which is accompanied by the plan. The assistant recorder then makes an exact copy of the original certificate, adding to it the words, "Owner's Duplicate Certificate," and delivers this to the owner.

Thus, the title to the parcel of land may be considered as being born again. From this time it is guaranteed by the State. The parcel thus started on a new career may contain only a few hundred square feet, or it may comprise several square miles, as the case may be.

GEODETIC CONTROL

From the beginning in Massachusetts it has been the aim to have all Land Court surveys made so that co-ordinate values could be computed relative to an assumed origin which might be one corner of the locus. The early instructions asked to have all surveys connected with recognized triangulation points when within or near the locus. When not connected with any recognized origin, then an origin within the survey is assumed and contiguous surveys is connected with it. This is carried on until the group of surveys, in turn, is connected with some local origin connected with the triangulation system, and then when these lands are thereafter dealt with, the lines are recomputed, based on the local origin. No request has been made to have local engineers use geodetic computations. Very few are acquainted with the formulas and they do not associate values in degrees, minutes, and seconds with small surveys, but rather with the U. S. Coast and Geodetic Survey work. If they are to carry on this horizontal system of control it must be made easy for them. Thus, the calculations for all reductions from geodetic values to plane co-ordinates have been simplified by the methods of the Massachusetts Geodetic Survey, as explained in Mr. Houdlette's paper. In many cases the necessary co-ordinates are furnished them before they begin a survey, especially if it covers a large area.

With the State divided into twenty-one registry districts, the system first adopted was to have an origin in the center of each so that all values would be relative to land registered and recorded in the respective registry of deeds. This system of rectangular co-ordinates was based upon a plane tangent to the earth's surface at a point. The area of each district was such that no appreciable error would appear on the exterior perimeter. The origin being a part of the State Triangulation system, the reduction from geodetic co-ordinates to plane co-ordinates was first made using the L.M.Z. formula (L.M.Z. has been adopted as representing latitude, longitude, and azimuth) and, later, by using formulas in *Special Publication No. 71*, issued by the United States Department of Commerce in 1921. This system was gradually being utilized by local engineers and by engineers working on the State highways.

In April, 1933, working in conjunction with the Department of Public Works a new system was adopted, as explained by Mr. Houdlette, whereby the State was divided into eight zones, but still using the plane rectangular system. The adoption of these new zones made it easier for the State engineers in crossing from one system to the other, as the number of origins were reduced from 21 to 8. It was also a step forward in having the highway network placed on a definite system referred to a common meridian, and if co-ordinate values were carried forward on subsequent highway plans they would have an economic value, appreciated by the engineer, but little realized by the owner of the land.

In December, the U. S. Coast and Geodetic Survey reported that all future values for triangulation stations in Massachusetts would be computed and published, as based on a new datum known as the North American datum, 1927. In using Government maps and geographical positions given in terms of latitude and longitude, especially in research work, engineers should, therefore, have in mind the three main projections used in Massachusetts, namely the Bessel spheroid used previous to 1880; the North American datum based on the Clarke spheroid adopted in 1880; and the North American datum, 1927.

In consequence, it was decided to adopt one uniform system of co-ordinates with values expressed in feet and fractions thereof, extending across the State. The projection advised by Dr. O. S. Adams, U. S. Coast and Geodetic Survey, as approved by the Massachusetts Department of Public Works and the Land Court, is defined as the Lambert Conformal Conic Projection of Clarke's spheroid of 1866, with two standard parallels held true to scale. This system is fully described by Mr. Houdlette.

CADASTRAL MAPS

The need for key maps upon which to plot the location of registered parcels was early recognized. All the available commercial atlases of the towns, cities, and counties were purchased and upon these atlas sheets the lands sought to be registered were outlined in blue and the case number indicated. These atlases serve as a graphical index, not only for the use of the Court, but for the public as well, to ascertain whether any registered lands exist in any given locality.

In addition to these atlases, there have been made from time to time standard base maps, called cadastral plans. The basis for these plans is the geodetic control system and the fifty-four Topographical Sheets of the U. S. Geological Survey, which include the Commonwealth of Massachusetts.

These 15′ quadrangle sheets have been divided into nine lettered sections of 5′ each and each section is further divided into eight numbered plans. Thus, there are seventy-two plans to a topographical sheet, and the area covered by each plan is 2′ 30″ of longitude and 1′ 15″ of latitude. The scale for these plans is 300 ft to an inch which allows the use of standard paper, 27 in. by 40 in., with about 1-in. margin. On a decree plan the reference, "52-H-6," would indicate that the land as registered is plotted on Topographical Sheet 52, Section H, Plan 6.

These plans when first prepared show border lines of longitude and latitude, dimensions, in feet, on each side, and the rectangular co-ordinates of each corner intersection, as well as the sheet number, town names, and town boundaries. From these data, inside construction lines are plotted and the sheet is then ready for plotting any parcel or lines connected with the geodetic control. Existing maps upon which the geodetic lines appear may be easily enlarged and placed upon these plans.

SUBDIVISION PLANS

The Land Registration Act provides that a registered owner holding one certificate for several distinct parcels may surrender it and take out a certificate for each parcel; likewise, if he holds separate certificates for each parcel, he may surrender them and take out one certificate for all parcels or any number of them. The Act further provides that an owner who subdivides a tract of registered land into two or more lots shall file with the Court a plan thereof, when applying for a new certificate; that this plan shall be verified; and that all newly created boundaries and ways shall be distinctly and accurately shown thereon.

The original Certificate of Title describes with a bounding description the perimeter of the land registered, and this is true whether the decree plan shows one parcel containing 5 000 sq ft of land or 5 acres subdivided into, say, thirty numbered parcels. In the first case, if the parcel was conveyed, the owner would surrender his certificate; it would be canceled and a new certificate issued to the new owner, referring to the plan filed with the first certificate. This might happen many times.

In the second case, one or all of the thirty separate parcels as shown upon the decree plan might be conveyed to as many separate new owners. Each new owner would receive a certificate describing the parcel he had acquired and referring to it by Parcel No. * * *, Plan No. * * *, filed with Certificate of Title No. * * *. As each parcel was conveyed, a memorandum to that effect would be entered on the grantor's certificate giving the grantee's name, date, and other pertinent information. Likewise, all mortgages or other papers affecting the title would be entered, so that the state of the owner's title is always obtainable by first reading the owner's certificate and thus observing the nature of the encumbrances entered on its reverse. In many cases where mortgages have been registered, later discharged, and the parcels sold, the owner will surrender his certificate encumbered with all these references and ask that he have a new certificate, purged of all "dead wood," which after an examination by the Court is granted.

When the decree plan shows numbered parcels, or parcels and ways, separate Certificates of Title may be issued without any further Court order. The fact that the divisions are on the decree plan is the Assistant Recorder's authority. When, however, any parcel as registered and shown upon the decree plan is changed by creating new interior boundary lines, a new plan is required as described, and, at this time, the owner files with the Engineering Department of the Court his Certificate of Title, and the new plan. This certificate is examined to see if it covers the land shown on the plan as filed, and the plan itself is verified to see that it is consistent with the previous registration plans to which the certificate refers and that all new boundaries and ways are accurately shown with proper engineering data, the same as if a new petitioner's plan were being filed for original registration. Each new lot or parcel must be consistent in itself and the distances and angles indicated must be reasonable. If found correct in all these details it is approved and a plan made from it on standard-size white paper showing the new divisions with data appearing on the filed plan, and in many cases additional data appearing on the files of the Court. On this plan appears the legend:

> "Separate Certificates of Title may be issued for the numbered lots as shown hereon; or it may be for 'certain lots, *viz.*, Lots 24 and 25 as shown hereon'; as the case may be. This legend is attested by the Court."

This plan with the owner's Certificate of Title is sent to the Assistant Recorder for the district in which the land is situated with an order to cancel that part of any plan or plans upon which the land thus divided is shown. This process continues *ad infinitum*.

The subdivision plan work is an important and ever-increasing function of the Court. It is handled exclusively in the Engineering Department where in many instances complete descriptions based upon the new plan are furnished to the Assistant Recorders. The subdividing of land, the relocation of highways, the merging of contiguous parcels into one ownership, the re-arrangement of lots, the call for plans showing land remaining after a large tract has been actively dealt with, and the many other activities encountered in dealing with land and title create new plan work and the issuance of new Certificates of Title. This cancellation of the old or previous plans and the making of new plans is the means of continually keeping up to date the existing state of the title as well as the existing facts upon the ground, with newly acquired engineering data.

It is in dealing with subdivision plan work and the calculations incident thereto that the importance of a rectangular co-ordinate system, whether local or not, is impressed on the engineer. In many instances, the adoption by the State of one common projection to be used by all engineering agencies will prevent the duplication of survey work, which all engineers know exists at the present time.

Although a Land Court will quiet the title and make it indefeasible, a coordinate system such as is now recommended by the U. S. Coast and Geodetic Survey furnishes the foundation for all local and municipal surveys; eliminates the uncertainty of the magnetic meridian; provides a system for placing on plans the exact value of all corners, thus making property plans more valuable; provides a method of reproducing lines in areas devastated by fires; and, finally, tends to reduce materially the boundary line controversies which are so detrimental to the peace of a community, as a single point on the earth's surface furnishes a starting point for all surveys. Most disputes arise from a misinterpretation of the law controlling boundaries and a difference of opinion between engineers as to the starting point.

Doubtless problems of this general type were in the mind of Moses when he stated in "Deuteronomy" 27:17: "Cursed be he that removeth his neighbour's landmark, and all the people shall say, Amen."

DISCUSSION

H. J. Shea,[10] **Jun. Am. Soc. C. E.** (by letter).—In the face of such obstacles as had beset its path, the Massachusetts Geodetic Survey not only has triumphed, but has succeeded so well that the organization deserves a permanent place for the promulgation of engineering data in the Commonwealth of Massachusetts. Because of the haste with which the organization was instituted and the large number of parties operating in the field, the Home Office was shortly deluged with field observations. Recalling its early stages, it is not only a wonder that valuable data were forthcoming, but it is a marvel that the Massachusetts Geodetic Survey was able to extricate itself at all.

Massachusetts is indeed fortunate in having two excellent surveying agencies—the Massachusetts Geodetic Survey and the Land Court—both using the Lambert plane co-ordinates and advancing the engineering benefits of such a system. It is to be hoped that the Department of Public Works will be one of the first highway organizations to make widespread use of the Lambert co-ordinates. Such an application would obviate any duplication of data and would further efficient performance in this important public service.

However, the desired goal is not quite attained. Intelligent surveyors are after common applications of plane co-ordinates in point descriptions—those which concern the layman. The present problem is not one of "new surveying." No overhauling of specifications or methods of computations is necessary, but rather the problem appears to be the education of the every-day surveyor in the use of geodetic control through the translation of geodetic control into terms that are readily understood.

Perhaps the educational necessity involved may be inferred from a statement about the condition of control surveys in Great Britain. In a personal communication, the Brigadier of the Ordnance Survey states that geodetic control cannot be considered limited because it covers the entire country, as do the published plans. All the surveys of Great Britain are conducted from that office. Its large-scale property plans are published at the scale of 25 in. to the mile. Quoting the Brigadier:

> "They may need occasional addition and amplification by local authorities, but they are based on geodetic control and give graphically the positions of all important buildings and everything except the most recent developments in correct relative position. In England, the private surveyor is hardly ever called upon to take accurate measurements in the field."

Although the United States has no surveying unit similar in scope to the Ordnance Survey of Great Britain, the calculated effect of the present program should not be greatly different. Such a result may be obtained through unity of purpose in the various programs of surveying and the adoption of standard specifications.

---

[10] Instr. in Civ. Eng., Mass. Inst. Tech., Cambridge, Mass.

In modern precise surveying, the importance of accurate geodetic control has become increasingly great. Scientific and well-planned surveying units, municipal or private, are quick to recognize the advantages derived from a uniform surveying control. By geodetic control is meant the establishment of surveying data, obtained either by precise triangulation, traverse. or levels, adjusted to remove accidental errors and based on a uniform datum. The standards of such work are considered so high that subsequent and more divided surveys are based upon, and adjusted to, the fixed values of the control survey.

There is one point in the problem of establishing control surveys that should be clearly understood. The surveyor is in the nature of a public servant and is often forced to deal with people having less specialized training. Although geodetic methods of computation should be the foundation, because of the difficulty in handling such computations, the greater number of surveyors are unable to use geographic values efficiently. The impartial observer, at present, finds it difficult to agree with impatient statements relative to the inability of surveyors to cope with the specialized methods of geodesy. It must be remembered, however, that the results of surveying operations are not confined to specialists only, but to lawyers, land owners, and dealers—in short, every one connected with land is intimately concerned therewith. Through the winning of the layman's confidence, the success of the present program will be assured. Thus, for a widespread realization of the benefits of control surveys, it is important to present the subject on a sound common basis rather than await the training of specialized surveyors.

A plane co-ordinate system is the apparent answer to the problem. In evaluating the relative advantages of the various co-ordinate systems, primary consideration should be given to the ease of reference to basic geodetic values. Although various systems have been suggested adapting co-ordinates to surveying, at present the most widely used are the tangent plane, the Lambert conformal projection, and the transverse Mercator projection co-ordinates. Co-ordinates on the latter two systems are handled much the same way, one being adapted to States having greater east-and-west extent and the other to States having a greater north-and-south extent, respectively.

The characteristics of these systems may be compared in the following schedule, in which (*a*) refers to the use of the tangent plane, and (*b*) refers to the use of the Lambert and transverse Mercator projection:

Basic Origin.—

(*a*) One local origin in the tangent plane. For wide use several tangent points are necessary (three are needed for New York, N. Y.).

(*b*) The Lambert and transverse Mercator are based on two geodetic parallels (or a meridian). One State system covers States as large as North Carolina or New Jersey.

Comprehension.—

(*a*) The tangent plane system is very easy to understand.

(*b*) Somewhat more difficult than the tangent plane but can be grasped readily with some study.

Computation of Points and Traverses.—

(*a*) Points are computed easily from geographic co-ordinates, but difficulty is encountered in traverses, because of the varying scales for which there is no definite mathematical treatment.

(*b*) Points and traverses are computed simply. There is a definite relation between grid and geodetic lengths. Angles are well maintained through the rectangular grid.

Extent.—

(*a*) Definitely limited and local.

(*b*) State-wide; and basically national through ease of transfer from one system to another.

Basic Tables.—

(*a*) The basic tables are excellent through the use of U. S. Coast and Geodetic Survey *Special Publication No. 71.*

(*b*) Excellent through use of various State tables. Noteworthy of mention are the tables prepared in 1937 giving the plane co-ordinates of minute intersections of meridians of longitude and parallels of latitude published by the Massachusetts Geodetic Survey. This publication reduces the calculation of plane co-ordinates from geodetic points to mechanical interpolation.

Adjustment.—

(*a*) Well adapted to adjustment, but dependability of adjusted values varies because of poorly determined scale effect.

(*b*) Well adapted. Adjustments may be made directly with co-ordinate values on the grid. Subsequent geodetic values are easily found.

Publication of Co-Ordinates.—

(*a*) Comprehensive list may be formed, but strictly local in scope.

(*b*) State-wide publication possible.

At present, one disadvantage in the education of surveyors into the use of the Lambert and the transverse Mercator projection co-ordinates seems to be the necessity for the reduction of geodetic lengths to grid lengths. It should be emphasized that the scale factors represent, not errors, but scale variations—mathematically exact in their relation to the geodetic values, free from any such stigma as "errors," easily applied to measured distances. Any inference of the existence of errors in the Lambert and transverse Mercator projections must be strongly rejected.

The legal aspect of geodetic control is perhaps one of the most potent factors in its favor. Land, certainly a common article of transfer, is often sold and bought without definite knowledge of the area, the protection afforded, and the surety that the deed description entitles the grantee to the property sometimes so vaguely described. Without attempting to draw "hard and fast" lines, the types of deed descriptions of property may be classified into four categories (seemingly in order of diminishing frequency); namely, land descriptions which, when without the original monuments or ties to the original monuments, are: (1) Not retraceable; (2) replaceable if a sufficient number of original monuments are recovered; (3) replaceable if one property monument is found or is replaceable because of ties to some public monument; and, (4) replaceable because description gives co-ordinates of property corners in some comprehensive system based on geodetic control.

Existing land rights in Case (1) are based on the best evidence possible, and two different surveyors might give widely different interpretations. Cases (2) and (3) depend for their interpretation on the recognition of extant bounds. In Case (4) replacement is simple if horizontal control points are within reasonable distances.

An important benefit resulting from Case (4) would be an amelioration of the ethical standards of the Surveying Profession. Too little emphasis has been placed on the legal ownership of surveys, a fact considerably abused by practicing surveyors. Property corners described in a co-ordinate system based on geodetic control would certainly leave no doubt as to the meaning of the description and should increase the confidence of the property owner in the work of the surveyor.

Hitherto, monuments have been thought to be the ultimate in boundary and property demarcation; but has not surveying experience in every section of the United States demonstrated that loss or displacement of monuments through construction and natural causes is sufficiently frequent to instigate well-placed skepticism in the lasting properties of physical markers? With a universal and comprehensive system of property description based on the required use of State-wide co-ordinates, does it not seem possible that there is at last a definite goal—a surveying element "better than the monuments"?

Mr. Houdlette's paper is noteworthy as an outline of one of the best surveying units of its kind. It must be regarded, therefore, as a valuable paper and would serve well as a guide for similar State organizations.

Philip Kissam,[11] Assoc. M. Am. Soc. C. E. (by letter).—The importance to the public of closely spaced, previously determined survey control points, and definitely determined, mutually controlled, and permanently located boundary lines cannot be emphasized too strongly. This Symposium constitutes a description of an objective which must be ultimately attained throughout the United States. The advantages to be gained are obvious upon a moment's consideration.

It is evident that no survey is of use unless its precision is determined. Unless public survey control is available, individual control systems must be established for even the simplest project. If, on the other hand, standard, recognized control points of unimpeachable accuracy are established once and for all in a certain locality, all surveys made in that locality can be based on this control with the result that precision will be increased and survey costs reduced.

When once a survey has been completed, the data obtained cannot be combined with that of another survey unless both are based on the same system of control and preferably on the same datum. It is essential, therefore, that the control system, to be most effective, should be nation-wide so that in fact all surveys become part of one great survey. It will be noted that in the work that Mr. Houdlette describes, all control points, both vertical and horizontal, are connected with the national level, or triangulation net, so that the first requirement is abundantly fulfilled.

---

[11] Associate Prof., Civ. Eng., Princeton Univ., Princeton, N. J.

The utilization of the Massachusetts system of plane co-ordinates is an exceptionally important part of the project Mr. Houdlette describes. Practically all ordinary surveys are reduced to plane co-ordinates in order to determine their precision. It requires no more work or difficulty to use Massachusetts co-ordinates to make this reduction; but whenever Massachusetts co-ordinates are used for a survey, that survey is forever fixed in position and is correlated with every other survey so connected.

Perhaps the most important surveys of all are those made to define land boundaries. Property surveys are older than all others, and a large portion of the national wealth is dependent on their accuracy and permanence. Mr. Humphrey notes the set of rules he has worked out to be followed by land surveyors in making property surveys. Through these rules and by the able conduct of his office he has succeeded in developing a procedure and a type of land description which permanently locates land boundaries. Not only are the boundaries located definitely and permanently, but it is possible for any surveyor to re-mark the property corners by recourse to the description alone, and entirely without knowledge of local conditions. Those who are familiar with the archaic methods in common use to-day for making surveys and descriptions of land will recognize the singular importance of Mr. Humphrey's contribution.

One of the secrets of the success of the Massachusetts Land Court is the insistence of its engineer that durable monuments be established and that they be inter-connected by surveys so that they can be replaced when destroyed. Under his direction many local plane co-ordinate systems were developed, as noted by Mr. Houdlette. Quick to realize the importance of a universal datum, the Land Court now requires connection with the control points that the Massachusetts Geodetic Survey is establishing.

With this co-operation between the Land Court and the Massachusetts Geodetic Survey the cycle is complete. The Commonwealth of Massachusetts is being prepared for every type of survey requirement. It will be possible eventually to determine the relative position and elevation of every topographic feature or boundary line in the entire State with very little expenditure of time or money. It is evident that as these plans are developed, every survey made in the State will be correlated with the whole.

The Civil Engineering Profession cannot afford to overlook the advantages offered by this plan. If the profession is to take its proper place in public affairs every effort must be made to insure the establishment of these systems throughout the United States.

Lloyd G. Frost,[12] **Assoc. M. Am. Soc. C. E.** (by letter).—The splendid accomplishments of the Massachusetts Geodetic Survey, so ably set forth by the author, cannot be over-rated in their value to the Commonwealth of Massachusetts and to the long-neglected field of surveying and mapping, as well as to the profession at large. Mr. Houdlette has so clearly depicted the conditions that exist generally in the land-surveying field and the relation of a system of rectangular co-ordinates thereto that every engineer and surveyor, in the light of his own experience, will readily recognize the indisputable superiority of the co-ordinate method and look hopefully for extension of such State systems on a national scale.

---

[12] State Supervisor, Louisiana Geodetic Survey, New Orleans, La.

The Louisiana System of Plane Co-ordinates.—The Louisiana Geodetic Survey was established at the same time as the Massachusetts project and under like conditions. The same vicissitudes were met that visited themselves on the latter, and, in general, the details of organization and field procedure are parallel. Mr. Houdlette's description of the projection frame applies to that for Louisiana, except that the configuration of the State made two projections necessary—North and South. As with Massachusetts, the U. S. Coast and Geodetic Survey selected the projections and prepared the necessary tables of data for computations.

The difficulties encountered in securing competent personnel to perform the work adequately may have been somewhat greater in Louisiana because of the much larger area of the State, but the various obstacles were surmounted surprisingly well in the earlier stages of organization. The standards of accuracy maintained for the Louisiana project differ from those in Massachusetts and New Jersey,[13] as indicated by the following comparison (in which S is the distance run, in miles):

	Traverse	Levels
Louisiana	1 : 20 000	$0.25 \sqrt{S}$
Massachusetts	1 : 10 000	$0.4 \sqrt{S}$
New Jersey	1 : 10 000	$0.3 \sqrt{S}$

The interval between stations in the Louisiana network varied from 0.5 mile to 1 mile during the early years of the program. Experience showed that in many cases these distances were too great to permit maximum availability to the local user, and the optimum interval was set at 0.25 mile except in certain unusual cases. Wherever time and facilities permit, longer tangents are being broken down to this standard.

The strength of field forces in Louisiana varied from an average of fifteen parties to a maximum of thirty during a short period in 1936–1937. In February, 1938, a reduction was made to ten parties in a reorganization effected to increase efficiency.

The work accomplished by the Survey, through September, 1938, in comparison with that given by Mr. Houdlette for Massachusetts is as follows:

Traverse:	
Extent, in miles	5 964.82
Number of stations established	12 234
Miles of traverse with preliminary co-ordinates	531
Miles of traverse with final co-ordinates	3 754.72
Average closure error	1 : 35 000
Bench-Marks:	
Extent of second-order levels, in miles	5 964.82
Number of bench-marks	14 681

---

[13] *Bulletin No. 46*, New Jersey State Dept. of Conservation, 1938.

Protracted study of the system of field procedure led to the conviction in February, 1938, that maximum efficiency was not being attained. The field organization, unvaried since the beginning of the project, was as follows at that time:

Each party consisted of ten men—a chief of party, transitman, levelman, and seven rodmen and chainmen; transportation was by owner-operated truck, the driver working as chainman; and each party was provided with one transit and one level.

The methods of geodetic surveying necessary to insure the required standards of accuracy would not permit doing the various operations simultaneously with this number of men. There appeared to be a considerable waste of time that was unavoidable under the conditions. At no time since the inception of the project did the records of work performed indicate a rate of progress consistent with the number of men engaged on the work. The available funds did not permit any appreciable changes at that time, but it was decided to institute some investigations and experiments in anticipation of a new appropriation.

Two parties were chosen as "guinea pigs," and the personnel increased to seventeen men, classified as follows: Observation section—chief of party, recorder, and two rodmen; measurement section—transitman, recorder, two chainmen, and three rodmen; level section—levelman, and two rodmen; and monumenting section—truckman, and two laborers. It was believed that a party so organized could carry on the several operations simultaneously with a maximum of efficiency and accuracy. The results obtained more than realized expectations and all parties operating in the State (fifteen in number) were reorganized on this basis. Two division engineers were appointed with headquarters in the northern and southern parts of the State and intensive supervision of field operations instituted.

Each party was supplied with two transits and other necessary equipment to conduct the work with a minimum of lost motion and duplication of effort. Indications are that these parties, comprising a total of 255 men, will perform considerably more work than thirty parties of ten men each. The proportionate saving in cost is greater than indicated by the smaller personnel, due to reductions in the higher brackets of salaries, and in transportation costs.

Most important of all is the time factor—experience thus far (1938) leads to the conclusion that it will be reduced by one-half.

No triangulation has been attempted by the Louisiana Geodetic Survey. The 1938 winter program of the U. S. Coast and Geodetic Survey contemplates completing the Louisiana network. One party has been engaged in first-order traverse for about one year.

Publication of Geodetic Data.—A constantly increasing demand for station descriptions created such a burden of clerical work that it became necessary to establish some method of placing the accumulated data at the disposal of users in a compact and accessible form.

After a study of available means of distribution, it was decided to issue a series of geodetic quadrangles, enclosing 0° 15′ of latitude and longitude, identical in geographic position, nomenclature, and scale with those of the U. S. Corps of Engineers and the U. S. Geological Survey. A total of 208 such quadrangles was required to cover the State and, in addition, a series of three-minute quadrangles (6 in. to the mile), covering the more important municipal areas, will be published.

Quadrangles are printed in black and white with all water in blue. All control points are located and identified and sufficient topographic information, together with subdivision lines of the rectangular land office surveys, are shown to insure facility in selecting control points for any purpose. The reverse of each quadrangle bears complete geodetic data for each station.

The location of rectangular survey lines is from original township plats, adjusted to field ties made by the U. S. Geological Survey, the State Board of Engineers, the U. S. Corps of Engineers, and the Louisiana Geodetic Survey, and topography from controlled aerial survey data is from the same sources. In addition to the quadrangles an index or key map is published, bearing on its reverse side a brief explanation of the method of using the data. Mimeographed descriptions of reference marks are available with each quadrangle. The user thus has at hand a graphic portrayal of the available control points in the section where he proposes to work, together with ties to facilitate locating them in the field, and the data necessary for their use.

Land Ties.—The original rectangular surveys in Louisiana date back as far as 1806. Prior to this time innumerable grants had been made and surveyed under Spanish and French rule. Where the "vara" obtained in early Texas surveys, the "arpent" was the unit of measure used in Louisiana prior to the United States Land Office subdivision.

Because of the type of instruments available, and other factors, familiar to every engineer, that influenced the making of early surveys, the conditions existing in Louisiana with reference to identifiable land corners and markers were confusing and discouraging until the present co-ordinate system was established.

Wherever it is possible to locate and identify original corners authentically, they are tied to the control network. The special marker shown in Fig. 6(*c*) is used, and at a satisfactory distance (usually between 400 ft and 500 ft) a reference marker (Fig. 6(*d*)) is set. The co-ordinates of all such corners are included with the data on the corresponding quadrangles, together with the azimuth of the reference point. This enables the engineer or surveyor to start from any such corner with a known position and a true bearing.

Many amusing (and at times appalling) discrepancies are encountered in adjusting the original surveys to actual positions determined by geodetic methods. There have been instances, furthermore, in which the work of the early surveyor stood up amazingly well. Within the life of the Survey, all original corners that can be located will be thus included in the original network.

State Boundaries.—That part of the boundary between the Republic of Texas and Louisiana north of, and not formed by, the Sabine River, was surveyed prior to 1845. Earthen mounds about 5 ft high and 15 ft in diameter were established at intervals of 1 mile. A traverse of this boundary has been run by the Louisiana Geodetic Survey, and monuments bearing the names of the Governor of Texas or of Louisiana on traverse markers (Fig. 6(*b*)) are established in all existing mounds.

That there were markers used other than mounds is evidenced by the discovery of a marble monument, 12 in. by 12 in., projecting well above the ground, and marked on the east "Louisiana" and on the west "Republic of Texas." The location of this boundary by plane co-ordinates is important not only as a State line, but as a line of demarcation across the rectangular subdivisions, and great care is being observed to locate and connect all land corners near-by.

FIG. 6

The northern boundary of the State was included in this traverse. Although it was well monumented, there were no available data on geographic location of these points and their connection to the control network was important and necessary. That part of the northern boundary east of the Mississippi River is controlled as a line of latitude and it will be run and monumented as such.

Legal Recognition.—The New Jersey Legislature has enacted legislation establishing the plane co-ordinate system in that State as the base of all surveys.

Such an act was for presentation to the 1939 session of the Louisiana Legislature, incorporating provisions to guarantee work ability and penalties for non-observance. The legislature of 1918 enacted legislation which is applicable to field operations of the Louisiana Geodetic Survey in granting rights of entry and affording protection of monuments and structures.

Use of Information.—In Massachusetts, New Jersey, and elsewhere keen appreciation has been evidenced of the vital importance of making all accumulated data easily accessible so that its application can be made universal. In his conclusion Mr. Houdlette states that in Massachusetts the control stations are located on individual town maps, together with available data. It is the writer's understanding that the Commonwealth of Massachusetts is divided into about 300 "towns"; Louisiana, with its much greater area, is divided into 64 "Parishes." Plotting of control data to a suitable scale on Parish maps would have resulted in such maps being too cumbersome for convenient use, irregular in size and bearing no definite relation to other compilations of related data.

The quadrangle system, as adopted, appears to be loosely comparable to the Massachusetts town system, except in one particular, which is of importance in Louisiana. Exploration for oil and minerals has extended into all parts of the State, as well as large-scale surveys for other purposes. In nearly all these operations, engineers are dependent upon the quadrangles of the U. S. Engineer Corps and the U. S. Geological Survey for topographical and cultural data, and upon the control of the U. S. Coast and Geodetic Survey and the Louisiana Geodetic Survey. The compilation of geodetic information upon identical quadrangles achieves a uniformity in size, location, scale, and area of base maps that is of considerable value to the user.

A "consummation devoutly to be wished" is the publication, by every State, of a uniform series of maps bearing geodetic information based on plane coordinate systems such as Mr. Houdlette describes, the whole to form the base for a series of topographic and cadastral maps on a nation-wide scale.

To this end Mr. Houdlette's paper, in recounting the accomplishments of Massachusetts, may prove to be of no small value in arousing realization of the need for such a program and in helping to point the way.

The Louisiana Geodetic Survey is sponsored by the Louisiana Highway Commission (Harry B. Henderlite, M. Am. Soc. C. E., State Highway Engineer) with the assistance and co-operation of the State Department of Conservation, the State Board of Engineers, and the Orleans Levee Board of the City of New Orleans, La.

William Bowie,[14] M. Am. Soc. C. E. (by letter).—The story told by Mr. Houdlette should be given thoughtful consideration by all engineers and other users of land, and by the officials of States, counties, and cities, whose duties include the advancement of the welfare of their citizens. After many years of effort on the part of a few engineers and planners to arouse the governing bodies of the United States to the desperate mapping and surveying situation, at last something is being done about it in at least a few States and political subdivisions.

---

[14] Hydrographic and Geodetic Engr., U. S. Coast and Geodetic Survey (Retired), Washington, D. C.

The opportunity came when the Administration, late in 1933, sought work that could be done by engineers and others who were unemployed. Geodetic surveys were suggested as professional projects that would provide jobs for thousands of idle engineers. Work was organized in all of the States by the officials of the U. S. Coast and Geodetic Survey, with a local director in each State. Within less than two months after the start, more than 10 000 persons had been employed, and of these, more than 8 000 were engineers and other college and university men and women. The project was a Federal one. The State directors were given wide authority as to who should be employed, and were authorized to discharge any one who could not, or would not, perform services that met their requirements. After a few months the project ceased to be under the Federal jurisdiction, and was turned over to the States, cities, and counties. It is to the lasting credit of those in charge of the subsequent projects that they carried on in the face of great difficulties and discouragements. In several States and counties comprehensive geodetic surveys have been made. Massachusetts is one of the outstanding ones.

The U. S. Coast and Geodetic Survey prescribed specifications for the geodetic surveys that would give to the results an accuracy needed for all except the most accurate surveying that might be based on them. It was required that the error of closing of a line of traverse should not be greater than $\frac{1}{10\,000}$. This is a greater accuracy than is obtained on most local alignment surveys made for construction and land boundary. The emergency geodetic surveys proved that this accuracy could be obtained with the equipment in common use by engineers. In Massachusetts Mr. Houdlette required a greater accuracy than that prescribed by the U. S. Coast and Geodetic Survey. This led to his securing an average closing error of only $\frac{1}{35\,400}$ for his traverses. The extra effort expended in improving the closures was more than justified. The work will not have to be repeated in the future, and the results will meet the most exacting needs of the engineer and surveyor.

The minimum limit of closure was set at $\frac{1}{10\,000}$ because it was felt that in some States it would be difficult to find engineers who could begin immediately to produce surveys of higher accuracy. Even the $\frac{1}{10\,000}$ survey was a severe problem for some of the directors. One of them reported that he could not find a single engineer in his State, eligible for relief employment, who could run a traverse with the required accuracy. A few men had to be trained first to do the work in a satisfactory manner, and then used to train others. The writer cites this to show to what a low ebb the surveying of this country had fallen. Several millions of dollars have been spent on the relief geodetic surveys and valuable results have been secured in several States. The unit costs have been higher than if the work had been done under normal employment conditions, but the educational value alone of the emergency geodetic surveys more than justified the expenditure.

It cannot be expected that the States and their political subdivisions will continue indefinitely to receive relief funds for making geodetic surveys; but those surveys should be continued until there is a traverse or triangulation station within easy reach of the engineer or surveyor who may wish to have his work co-ordinated with surveys made by others in the same region. This means that in each State there should be an agency charged with the duties of making geodetic surveys, and furnishing information to those needing it. Such an agency should have authority to set minimum limits of accuracy for all agencies of the State Government that make surveys for engineering operations, and for the location or re-running of the boundaries of public and private property. If a few traverse parties in a State should operate continuously for five or ten years much could be accomplished. So many uses would be found for the results that there would be no difficulty in finding support for the completion of the work for the State.

One of the urgent needs of most of the States is the establishment of Land Courts. In a most interesting manner, Mr. Humphrey has described the Court dealing with title to land in Massachusetts, and the surveying that is done for the Court. Each State may well create a Land Court after the Massachusetts pattern. It would be a boon to engineers who have as their primary function the placing of valuable structures on the land. They should be sure that they have the boundaries accurately defined and located before starting their work.

Massachusetts is to be commended and congratulated for having sensed the importance of good land surveys, and for giving the effort necessary to make such work effective.

In recent years, the Society has published a number of papers that have told of the chaotic condition of land boundary surveys in such States as North Carolina,[15] Florida,[16] Massachusetts,[17] and Texas.[18] No doubt the conditions they portray are the same as in the other States. The writer knows of no State in which satisfactory surveys have been made on any comprehensive plan.

Mr. Houdlette has justly stressed the difficulty of using the national triangulation net as the base for local surveys on the system of spherical coordinates; but that difficulty has been overcome by devising State Plane Co-ordinate Systems. The engineer engaged on local surveys can use the plane co-ordinates of the triangulation and traverse stations, and needs to pay no attention to the computations that are involved in the transfer of spherical to plane co-ordinates. That work is done for him by the mathematicians of the U. S. Coast and Geodetic Survey or agencies like the Geodetic Survey of Massachusetts. There is really no excuse on the part of responsible officials of a State for delaying the adoption of plane co-ordinates, and the private engineer is doing himself a disservice if he does not use them.

[16] *Loc. cit.*, July, 1938, p. 451; June, 1938, p. 386; and May, 1938, p. 331.

[17] *Loc. cit.*, December, 1937, p. 824.

[18] *Loc. cit.*, November, 1938, p. 722; and July, 1937, p. 507.

There is now widespread sentiment in favor of better survey methods, and this sentiment will soon be translated into action. One of the first steps to be taken to bring better conditions into being should be the completion of the National Triangulation net. In the past, the triangulation has been considered by some as merely the frame for the topographic mapping; but the triangulation has so many other uses that it should be finished as soon as possible and not merely meet the demands of the topographic engineers of the Federal Government. The plan for the triangulation calls for the spacing of the arcs of triangulation at intervals of about 25 miles. This is the immediate objective, but the ultimate one is that eventually there will be no place east of the Rocky Mountains more than 6 miles from a station, whereas this distance is increased to 12 miles in the mountainous regions. This spacing is considered as desirable for the control of the maps that will be compiled from photographs taken from the air. Such spacing of the triangulation stations will make it possible for the engineers of the State Governments to have traverses run between pairs of stations, along railroads and highways, for the purpose of setting many stations along the routes for use by engineers and surveyors engaged on local surveying for engineering and land boundary work.

Perhaps no one is to blame for the slip-shod surveying that has been done in the United States during the past hundred years, but the bad practice should not be continued. The Corps of Engineers of the U. S. Army has been making surveys for river and harbor improvement and flood protection for many years, and, although the surveys have met their immediate needs, in most cases they were of a low order of accuracy, and in most instances no permanent monuments were left on the ground. This triangulation or traverse cannot add much to the national horizontal control system of the country.

The Topographic Branch of the U. S. Geological Survey has done an enormous amount of control surveying for its topographic mapping; yet only a very small percentage of this has been of such a standard as to make the results of value to the engineer or surveyor who is making surveys for engineering work and land boundaries. In their old work they left few or no permanent monuments. They should not be blamed for doing work with no more accuracy than was just sufficient for their small-scale mapping. They received a pitifully small sum of money for their mapping, so they could not divert much of it to the control surveying. Since there are so many needs for the results of the control surveys, however, the Geological Survey should strengthen its work in this respect. This applies also to the control surveys made by the Corps of Engineers.

If the objectives outlined by Messrs. Houdlette and Humphrey are to be reached in each of the States, all State agencies, such as the Highway Department, should make their control surveys with the accuracy needed to meet future use of the data secured. To do this would cost the State very little additional. The first step would be to purchase good instruments. The day of the 1-min transit, the non-standardized tape, the old-fashioned level, and the wooden leveling rod, has passed just as the day of the wheelbarrow and the ox cart has passed. To continue to use the old types of instruments is bad practice and wasteful. Either poor results are obtained, or an undue length of time is taken to secure accurate results. In every branch of engineering except surveying and mapping the best available instruments, machines, and equipment are bought and used. It is costing money to continue the use of surveying instruments that were scarcely up to date even two generations ago.

Although standards of surveying have been low, there is no cause to be pessimistic over the mapping and surveying situation. There are dozens of engineers and surveyors to-day who are making strong efforts to put better methods into practice, whereas until quite recently there were few who even knew there were problems to be solved. This Symposium is an indication of awakening interest in about the oldest and the most neglected branch of engineering.

R. M. WILSON,[19] M. AM. SOC. C. E. (by letter).—One of the successful projects that grew from seeds sown in 1933, in each of the 48 States, by the U. S. Coast and Geodetic Survey under an appropriation by the former U. S. Civil Works Administration, is described by Mr. Houdlette. In several States these seeds fell upon fertile soil, as they did in Massachusetts. There they sprouted and were carefully cultivated, even without the continued support of funds from the Civil Works Administration, and they have lived to bear valuable fruit.

The Massachusetts Geodetic Survey is a credit to those who have supported and administered it not only because of its success as a relief project but also because of the quantity and high quality of the work done. The supplementary control surveys that have been completed will surely repay the State of Massachusetts for its support of the project. The uses of the new geodetic control in connection with cadastral surveys and land titles have been described by both authors of the Symposium; much of the valuable harvest that the State will reap will be through these uses.

At present (1939) there is in progress, also, a program of re-mapping by the Geological Survey of the United States Department of the Interior in co-operation with the State of Massachusetts for the purpose of making, by modern methods, up-to-date topographic maps of the State. Control surveys are needed for this new mapping, and ordinarily it would be necessary for the Geological Survey to spend considerable sums of money for the required preliminary surveys before the actual mapping could begin; but with the results of adequate control surveys made by the Massachusetts Geodetic Survey already available, a larger proportion of the funds appropriated for mapping can be applied toward the primary purpose of the program. In this way, also, the State is reaping a genuine harvest because it cultivated the project that has become the Massachusetts Geodetic Survey.

In his historical sketch of early surveys in Massachusetts, Mr. Houdlette makes a statement that may be misleading to those who are not familiar with the facts. In his reference to the mapping authorized in 1884, he conveys the impression that the co-operative agreement was between the State and the U. S. Coast and Geodetic Survey, then a bureau of the U. S. Treasury Department; but Chapter 72 of the Acts of 1884 of the Massachusetts Legislature provided for the mapping of the State in co-operation with the U. S. Geological Survey, not the U. S. Coast and Geodetic Survey.

---

[19] Chf., Section of Computing, U. S. Geological Survey, Washington, D. C.

That agreement, made in 1884, produced the original topographic "quadrangle" maps of Massachusetts which were published by the Geological Survey. They are known to all map users in the State, and their popularity is attested by the large number of copies that have been distributed since they first became available, shortly after the completion of the field surveys in 1888.

The co-operative agreement, defined by Chapter 72 of the Acts, is an important one in the history of the U. S. Geological Survey. It was the first of the agreements of its kind made with States wishing to expedite topographic mapping within their borders. The success of the program established it as a model for co-operative agreements with other States, and many similar agreements have since been made. At present the U. S. Geological Survey has co-operative agreements for the making of topographic maps with 17 States and with Puerto Rico. One of these has resulted in the new co-operative mapping program previously mentioned.

The new program in Massachusetts has been undertaken because the existing maps on a scale of about 1 mile to the inch, which were made between 1884 and 1888, do not meet the exacting modern requirements. The new maps, published on larger scales with smaller contour intervals, permit the showing of greater detail and are up to date in showing developments in the works of Man. Thus, they are more nearly consistent with the present economic importance of the areas they represent. The 192 separate sheets, whole and fractional, that will be required to show the entire State, are first reproduced as lithographs on a scale of 1 : 24 000. To the present time, 51 have been reproduced as unedited advance sheets in two colors. Beginning now (1939), however, the advance sheets will be edited and reproduced as three-color lithographs. The final publications are engraved maps on a scale of 1 : 31 680.

ELLIOTT B. ROBERTS,[20] M. AM. SOC. C. E. (by letter).—Added emphasis may well be given one aspect of the subject treated by Mr. Houdlette. Reference is made to the difficulties experienced in the past by those who have tried to popularize the use of geodetic control for the correlation of local surveys; namely (1) inadequate distribution of geodetic control points, and (2) a widespread reluctance of surveyors to undertake the somewhat specialized computation necessary in adapting geographic position data.

Mr. Houdlette's organization has gone far to remove the first of these difficulties in Massachusetts, and a few more years of such work may well see the State so well supplied with control points that few, if any, surveyors could conscientiously avoid controlling their work by use of the national geodetic datum. The U. S. Coast and Geodetic Survey, in designing adequate plane co-ordinate projections for the States, and publishing tables relating thereto, has largely resolved the second difficulty. When that Bureau completes its intended publication of the plane co-ordinates of all its triangulation stations, it will have done so completely. Naturally the well-known operations of so diligent an organization as the Massachusetts Geodetic Survey are a tremendous added force in popularizing the plane co-ordinate projection in Massachusetts.

---

[20] Hydrographic and Geodetic Engr., U. S. Coast and Geodetic Survey, Washington, D. C.

The emphasis intended to be given by this discussion is to the fact advanced by Mr. Houdlette that, with abundant local control points defined in plane co-ordinates, the local surveyor, to use them, has no specialized computations to make, no new surveying process to learn, and nothing unusual to do but to start from the nearest control points instead of at random. From there on he may make the usual survey, computing latitudes and departures in conventional manner, and adjusting for the closure errors as he has always done. He may make a perfectly traditional plane survey; yet there is the tremendously important difference that his work is on a standard grid rather than an arbitrary local one. His work is based on the national datum, and is therefore correlated with every other such controlled survey throughout the entire country. This simple innovation, therefore, can eliminate the multiplicity of origins, mostly unrelated, the over-supply of height datums, and the economic loss of thousands of uncontrolled surveys of only momentary value.

The foregoing is so simple that it may seem a trivial point. The writer has observed, however, that many engineers are preoccupied with technicalities and fail to "pound home" the simple fundamentals necessary to impress others. The simple fundamental here is that by accepting a standard origin and coordinate system instead of setting up local ones of their own, surveyors can reap great benefits. This truth should be shouted, figuratively, from the housetops, so that surveyors may be persuaded henceforth to work in harmony instead of at cross purposes.

Mr. Houdlette is to be congratulated for the untiring productive work he has done, and for his excellent presentation of the subject. It is to be hoped that similar programs may be adopted in all the States. Massachusetts is learning that planning pays, in surveying as well as otherwise, and all the States should become aware of the great unnecessary cost attending the present haphazard methods.

AMERICAN SOCIETY OF CIVIL ENGINEERS

Paper No. 2068

ENGINEERING GEOLOGY PROBLEMS AT CONCHAS DAM, NEW MEXICO

By Irving B. Crosby,[1] Affiliate, Am. Soc. C. E.

With Discussion by Messrs. H. L. Johnson, and Irving B. Crosby.

Synopsis

None of the varied types of foundation conditions of large dams presents more difficult problems than those of dams on uncemented shale or siltstone, and perhaps in no other branch of Engineering Geology is there more need of additional research. The principal purpose of this paper is to describe some of these problems, using Conchas Dam as an example, to explain how they were investigated and met in this particular instance, and to outline the research necessary to solve similar problems more adequately in the future. In addition, this paper outlines some of the problems encountered with high dams on sandstone containing water under artesian pressure, since Conchas Dam rests on both shale and sandstone.

Introduction

Conchas Dam is a project of the United States Army Engineers on the South Canadian River 30 miles northwest of Tucumcari, N. Mex., designed to regulate and utilize the flood waters of the river. The dam is nearly a quarter of a mile below the mouth of the Conchas River, at a point where the South Canadian River turns from a southerly to an easterly course. The length of the river above its junction with the North Canadian River is 700 miles, of which only 150 miles are in New Mexico. Its basin is wider in the upper part, however, with the result that 51% of the drainage area and all the major tributaries are in New Mexico. Flash floods of great magnitude are common, but during much of the year the river is nearly dry. The greatest recorded flood had a peak flow of 279 000 cu ft per sec at the dam site. The climate is semi-arid, the annual rainfall being less than 15 in., but the river has its sources in high mountains where the precipitation is somewhat greater.

The main dam is a gravity, concrete structure 240 ft high and 1 250 ft long with the crest of the parapet at Elevation 4 240, and an uncontrolled

over-fall spillway 340 ft long with a crest elevation of 4 201 ft. Earth wing-dams connect with both ends of the main dam and the South Dike extends 6 400 ft from the South Wing-Dam (see Fig. 1). In addition, north of the Main Dam there is a concrete Emergency Spillway 3 000 ft long with earth dikes at either end. At the south end of the South Dike are the Irrigation Headworks and beyond is a small dike in a saddle. The earth wing-dams and dikes, the highest of which will be 96 ft, total 3 miles in length.

FIG. 1.—CONCHAS DAM AND DIKES

FIG. 2.—VIEW OF MAIN DAM, FACING UP STREAM, DECEMBER 24, 1937

The main concrete dam crosses the canyon of the river and rises above the walls of the canyon, the wing-dams extending to higher ground on either side (see Figs. 2 and 3). The main dam contains approximately 750 000 cu yd of concrete and the emergency spillway and irrigation headworks contain nearly 80 000 cu yd of additional concrete, making a total of 830 000 cu yd. The wing-dams and dikes contain approximately 2 900 000 cu yd of earth-fill and 790 000 cu yd of rock-fill.

When full, the reservoir extends about 14 miles up the South Canadian River and 11 miles up the Conchas River, but the valley of the Conchas River provides the greater part of the storage capacity due to its greater width. Above the dam site the South Canadian River is generally in a narrow canyon from 100 to 200 ft deep. The total storage capacity will be approximately 600 000 acre-ft. Of this, 100 000 acre-ft is dead storage, 300 000 acre-ft is irrigation storage, and 200 000 acre-ft, flood control storage.

FIG. 3.—GEOLOGICAL SECTION ACROSS CANYON ON LINE OF CONCHAS DAM

Preliminary work was begun with Government forces in August, 1935, and a contract was let for the main dam and wing-dams on October 6, 1936. Additional information about the purpose of the project, its history, the engineering and construction features, and the hydrology can be found in papers by John R. Noyes,[2] Assoc. M. Am. Soc. C. E., and by Gerard H. Matthes,[3] M. Am. Soc. C. E.

The project has been in charge of Hans Kramer, M. Am. Soc. C. E., District Engineer, Conchas District. James H. Stratton, Assoc. M. Am. Soc. C. E., was Chief of the Engineering Division until May 15, 1937, when he was succeeded by Captain L. H. Foote. J. B. Alexander, Assoc. M. Am. Soc. C. E., has been Planning Chief and H. V. Pittman, M. Am. Soc. C. E., Construction Chief. Joel D. Justin, W. H. McAlpine, William Gerig, H. T. Cory, Gerard H. Matthes, Members, Am. Soc. C. E., and the late Louis C. Hill, Past-President, Am. Soc. C. E., were Consulting Engineers, and the writer was Consulting Geologist.

GEOLOGY OF THE DAM SITE

Conchas Dam is in an extensive area of flat-lying sedimentary rocks known as the Red Beds. The rocks at the site are members of the Dockum

---

[2] "Conchas Dam and Reservoir Project," by John R. Noyes, *Engineering News-Record*, April 15, 1937, pp. 541–545.

[3] "Problems at Conchas Dam," by Gerard H. Matthes, *Civil Engineering*, July, 1936, pp. 437–441.

Group of Triassic Age. For convenience, the different members of this formation at the dam site were given local, descriptive names which are, beginning with the youngest and highest:

(1) Townsite Formation (sandstones and shales about 450 ft thick);
(2) Variegated Formation (shales with some sandstone about 300 ft thick);
(3) Canyon Sandstone (about 100 ft thick where not eroded);
(4) Upper Red Shale (average thickness, 64 ft);
(5) Pink Shaly Sandstone (average thickness, 25 ft);
(6) Upper Artesian Sandstone (average thickness, 64 ft);
(7) Lower Red Shale (average thickness, 30 ft); and,
(8) Lower Artesian Sandstone (thickness greater than 100 ft).

The canyon sandstone, upper red shale, and pink shaly sandstone outcrop at the main dam site, and the upper artesian sandstone was uncovered in the excavations. The lower red shale and the lower artesian sandstone underlie the dam site, and the South Dike is on the variegated formation.

The canyon sandstone is the rim rock of the canyon and, in general, is a hard grayish to brownish, massive sandstone; some parts of it, however, are thin bedded and softer. Where not fractured, it is a strong foundation rock and the practical problems concerning it have to do with the cracks which intersect it, and with the fact that it rests upon a weak formation.

The upper red shale is almost entirely devoid of the laminations typical of shale and, except for a few green strata, it appears unstratified. It consists, on the average, of 35% clay sizes (less than 0.005 mm), 45% silt sizes (0.005 to 0.05 mm), and 20% sand. Siltstone would be a more appropriate name than shale. The proportions of grain sizes vary considerably from place to place as do other characteristics of the shale. The percentage of clay sizes is greater in the south abutment than in the north abutment. The percentage of voids (that is, the ratio of the volume of voids to the total volume of the shale sample) varies both horizontally and vertically and is higher in the south abutment than in the north abutment. There is some tendency for the percentage of voids to be less in the lower part of the shale, but this characteristic is irregular in its distribution. The average percentage of voids in twenty-two samples of shale in the south abutment is 25.5; the maximum is 34.7, and the minimum, 12.6. The unit weight is 147 lb per cu ft in the natural condition. The average percentage of voids of forty-five samples from the north abutment is 17.6, the maximum being 26.0 and the minimum, 11.5. The specific gravity of the mineral grains averages 2.76. All the tests indicate that the shale is saturated with water. The red shale cracks upon exposure to air and crumbles to pieces. When re-wet, it breaks down to silt. If it is immersed in water in its natural condition without drying, however, it does not disintegrate. The most important foundation problems are concerned with this shale.

The pink shaly sandstone is an extremely variable formation ranging from a sandy shale to a fairly massive sandstone. It changes rapidly, both vertically and horizontally. Some parts disintegrate when dried and wet again, and other parts remain sound under such treatment. The practical problems are due to this variability. The shaly parts of it present problems similar to those of a typical laminated shale.

The upper artesian sandstone is a hard, gray, fine-to-medium grained, gritty sandstone with occasional flat shaly seams; but it is generally massively bedded. Shaly beds are more numerous in the upper part of the formation where they were a foundation problem. It was given its name because water under artesian pressure was encountered in the borings. This fact necessitated studies concerning uplift and seepage.

The lower red shale is similar to the upper red shale, and the lower artesian sandstone is similar to the upper artesian sandstone. The total thickness of this sandstone is unknown because none of the borings reached the bottom of it. Both these formations are at such depth that they cause no practical problems.

South and southeast of Conchas Dam the lower part of the Dockum Group and certain other formations contain gypsum, but no beds of gypsum were found at Conchas Dam. It is possible, however, that gypsum underlies the dam at great depth. The deepest boring reached 240 ft beneath the river without encountering gypsum, and it is certain that if any exists beneath the dam it is so deep that it will be harmless.

The formations at Conchas Dam were laid down essentially flat in water and have been slightly tilted and warped so that they now have a regional dip of about 2° to the southeast upon which have been superimposed gentle waves or folds. One of these folds brings soft rocks to the surface in the valley of the Conchas River, with the result that this valley is wider than the canyon of the Canadian River. No evidence of faulting was found near the dam site or in the reservoir basin, and the nearest known fault is 34 miles west.

The rocks at the dam site are intersected by fractures or joints running in various directions. These cracks are most numerous in the canyon sandstone and artesian sandstone and least developed in the red shale. The joints are most numerous in the directions N 50° W and N 40° E, and they are in general nearly vertical. The joints show every gradation from incipient planes of weakness to open cracks. In the canyon sandstone near the canyon wall where blocks of sandstone could move toward the unsupported edge, some of the cracks are gaping fissures.

There are comparatively few joints in the red shale, but there are numerous other fractures in various directions, and dipping at various angles. The characteristic fracture of the red shale is a short, curved, striated or slickensided fracture running in any direction and dipping at any angle. These fractures are generally from 1 in. to a few inches in length with a maximum length of about a foot. Similar slickensided fractures were produced in the Soils Laboratory at Conchas Dam by shearing a specimen of the red shale under a heavy transverse load. These fractures are evidently caused by very small movements.

The formations at the dam site were formerly buried by younger formations to a depth of at least 1 200 ft. Remnants of these younger and higher formations can be seen in the near-by mesas. Between the mesas is a broad undulating valley in which the river is entrenched in a canyon. Old river gravels give evidence that the river formerly flowed at the level of this old valley.

The dam crosses the canyon, rises above the canyon walls, and extends on to the cap rock on either side, as shown in Fig. 3. The central section of the high part of the dam is founded upon the upper artesian sandstone, but the two ends of the high section rest upon the pink shaly sandstone. The high section abuts against the canyon walls of red shale on either side of the canyon. The two ends of the dam which extend upon the cap rock will rest upon the canyon sandstone which overlies the red shale. From either end of the concrete dam, earth wing-dams extend to high land. The South Wing-Dam is on shale and sandstone of the variegated formation except for the northern end which rests upon the canyon sandstone. The North Wing-Dam is on the canyon sandstone, but the northern end will be against shale of the variegated formation.

The main part of the South Dike rests upon shale and sandstone of the variegated formation which provides a tight, satisfactory foundation for this structure. The southeasterly dip causes the top of the variegated formation to be lower at the south end of the South Dike, with the result that here the top is below the level of the crest of the dike and the south end of the dike rests upon sandstone of the townsite formation. The tunnel for the irrigation outlet is in shale of the variegated formation which is here overlain by a cap of townsite sandstone.

The Emergency Spillway rests upon the variegated shale and sandstone, but in places this is only a thin layer on the canyon sandstone and the foundation excavation was extended down to this sandstone. Where the spillway structure rests on shale the foundations were excavated to sufficient depth to remove the possibility of sliding of this low structure. These structures will not be discussed further since there are no interesting geological problems connected with them.

PRACTICAL PROBLEMS

The most important practical problems at the site of the main concrete structure were:

(*a*) The upper red shale as a foundation formation (its competency to support the design load, settlement of structures upon it, and the protection of the shale from disintegration);

(*b*) Seepage under the dam through the artesian sandstone, uplift pressure on the foundations of the dam from artesian water in this formation, and meeting these conditions by grouting and drainage; and the selection of foundation beds in this sandstone and in the overlying pink shaly sandstone, and the stability of structures resting upon them; and,

(*c*) Seepage under and around the dam through the canyon sandstone, and its prevention. Effect of the cracks in this formation on the stability of that part of the dam founded upon it.

Problems Connected with the Red Shale.—The red shale presented the most serious problems. It is an unlaminated siltstone which was deposited as a silty mud. Its consolidated condition is due to compaction and not to cementation. Following its deposition as mud other sediments were laid down upon it, and their weight compacted the mud, slowly squeezing the water out of the pores. As the compaction of the mud continued it became hard, silty clay and finally siltstone or shale. Erosion subsequently removed much of the load and the shale expanded somewhat but did not reach its original porosity. When load is again placed upon it there will be a renewal of compaction thus causing the settlement of any structure resting upon it. That part of the dam resting upon the shale will cause some compaction of the shale, with resultant slight settlement of the dam, even though the weight of the dam is much less than the weight of the overlying formations that have been removed.

Laboratory consolidation tests had been made on the shale from which estimates of settlement had been made, but there was some question as to the accuracy of these methods when applied to shale instead of to clay for which the tests had been designed; and it was desired to check the results.

From a consolidation test it is possible to estimate the load under which clay was originally consolidated.[4] Because of the close relationship between clay and uncemented shale it was possible to apply this method to this shale. In this case it was also possible to make an approximate estimate of the former load on the shale from field observations. Therefore, if these two estimates should agree there would be a check upon the laboratory method. The previous consolidation tests had been conducted with a maximum pressure of 25 tons per sq ft, and it was not possible to use higher pressures with the existing apparatus. It was evident that the original pressures were much higher and new apparatus was designed capable of testing the sample under a pressure greater than 100 tons per sq ft. The most reliable tests made with this apparatus indicated a former load of 64 to 70 tons per sq ft. Several miles south of the dam, Mesa Rica rises more than 1 200 ft above the river. The Ogallala Formation, the youngest known in this region, caps the highest part of the mesa. It is known that this high formation once extended unbroken to the Llano Estacado, about 15 miles to the south, and to the Canadian Escarpment 30 miles to the north. This high formation thus once overlay the dam site and it is possible to make an approximate estimate of the load that once rested upon the red shale. The difference of elevation between the summit of the mesa and the shale at the dam site is 1 250 ft, and this is the minimum over-burden on the red shale. Due to dip of the strata and other causes it may have been somewhat greater. Since the ground-water conditions at that time are unknown, the weight of this over-burden is not exactly known; but, using extreme assumptions gives values of 50 and 94 tons per sq ft for the two extreme conditions, with the most probable range between 60 and 70 tons per sq ft which checks with the laboratory estimate of 64 to 70 tons per sq ft and indicates that the laboratory tests are at least approximately correct.

Estimates of probable settlement of that part of the dam underlain by red shale were made by applying the laboratory results to the geological interpretation of the strata and gave a maximum settlement for extreme conditions of about 4 in. after a period of years. There will be differential settlement, therefore, between the parts of the dam underlain by the red shale and those parts resting directly upon the artesian sandstone. The condition being known, the dam was designed to meet them, and a special joint was devised between the different parts of the dam.[5] Differential movement between the monoliths underlain by the red shale and those resting upon the artesian sandstone can thus take place harmlessly.

---

[4] "The Structure of Clay and Its Importance in Foundation Engineering," by Arthur Casagrande, Assoc. M. Am. Soc. C. E., *Journal*, Boston Soc. C. E., April, 1932, Vol. 19, No. 4, pp. 176–179.

The strength of the shale—that is, its competency to support the load it will be required to carry—was studied by geological observations in the field and the conclusions were checked by laboratory tests and by computations. In the north abutment the red shale is about 70 ft thick, the sandstone cap rock averages 20 ft thick, and the dam rises 95 ft above this. Therefore, the load on the shale is 20 ft of sandstone and 95 ft of dam.

The canyon walls were studied for miles above the dam and places were found where the sandstone overlying the shale is more than 100 ft thick. Thus, there is proof that the shale is sustaining a load as great as, or greater than, that of the dam, without failure. The canyon walls generally break down by weathering of the shale. The shale cracks and disintegrates upon exposure to air, the sandstone cap is undermined, and large blocks tip and slide into the canyon. The only places seen where the walls had collapsed due to failure of the shale were where the stream had undercut the cliff, producing stresses greater than any that can exist in the shale under the dam. The field observations thus indicated that the red shale is strong enough to support the dam. This conclusion was checked by laboratory tests.

A series of shear tests and of unconfined compression tests on samples of the shale were made in the Soils Laboratory at the dam, with the results shown in Table 1. Compression tests were made on 2-in. cubes. The results for samples from different elevations, in both the north and south abutments, are given in Table 2.

TABLE 1.—SHEARING RESISTANCE, SAMPLES OF RED SHALE FROM THE NORTH ABUTMENT

(All Units Are Pounds per Square Inch)

Elevation, in feet, above mean sea level	Shearing Stress, for the Following Normal Loads:					
	50	75	100	125	150	157
4 110	218	253	263	287	290	...
4 084	202	260	220	292	...	337
4 065	185	242	242	310 327	...	...

A study was made of the stresses in the red shale under the action of the completed dam. The following assumptions and constants were used:

---

[5] For description of joint, see "Dam Building on Difficult Rock," *Engineering News-Record*, June 9, 1938, pp. 808–809.

(*a*) The net section of the non-overflow dam, without heel or toe fillets, was used; the foundation was assumed level at Elevation 4 140, which is the top of the canyon sandstone; and the bottom of sandstone was taken at Elevation 4 120, and the bottom of red clay shale at Elevation 4 050;

(*b*) The foundation materials were considered as homogeneous and isotropic, acting in agreement with Hooke's law;

(*c*) Five different classes of assumptions as to the distribution of stress at Elevation 4 140, and the effect of the sandstone in distributing the load at Elevation 4 120, were studied (see Cases I, II, III(*a*), III(*b*), and IV);

(*d*) The modulus of elasticity of the concrete, sandstone, and shale was assumed equal in Cases I, II, and III(*b*); and the modulus of elasticity of the shale was assumed to be one-third of the modulus of the sandstone or concrete in Cases III(*a*) and IV;

TABLE 2.—COMPRESSIVE STRENGTH OF RED SHALE, IN POUNDS PER SQUARE INCH

* Omitted from average.

(*e*) A cross-section of the dam and foundation was studied in each case, and no forces acting at right angles with the plane of the section were considered;

(*f*) Uplift and internal pore pressure were neglected;

(*g*) Unit weights were assumed at 62.5 lb per cu ft for water, and 150 lb per cu ft for concrete, sandstone, and shale; and,

(*h*) The reservoir was assumed permanently filled to Elevation 4 230 for the full reservoir condition.

The following possible assumptions as to stress distributions were considered:

Case I.—Straight line distribution of stress at Elevation 4 140 was assumed and the sandstone was considered effective in spreading the load. This case represents the minimum stress concentration that can exist in the shale foundation.

Case II.—Non-linear distribution of stress at Elevation 4 140 was assumed and the sandstone was considered effective in spreading the load. This case gives stress concentration at the toe and heel in the plane of the base, but considerable distribution before the load is transmitted to the shale.

Case III(a).—Non-linear distribution of stress at Elevation 4 120 was assumed. The sandstone above Elevation 4 120 was assumed to act with the dam, but to be ineffective in spreading the load on to the shale.

Case III(b).—All assumptions were the same as in Case III(*a*), except for the substitution of linear distribution for non-linear at Elevation 4 120.

Case IV.—In this case, non-linear distribution of stress at Elevation 4 120 was assumed. The sandstone above Elevation 4 120 was assumed to act with the dam, and was considered to be effective in spreading the load at 45° with the horizontal.

Stresses were computed for all these cases. Case I is less severe than actual conditions; the assumptions in Cases II and IV may closely approximate actual conditions; but Case III(*a*) is the most severe condition possible. The results obtained are conservative and are the ones given herein. The maximum computed shear stress in the shale at Elevation 4 120 is 138 lb per sq in. The average shearing strength as computed from unconfined compression tests on twenty 2-in. cubes was 266 lb per sq in. This is for material unconfined, but at the point of maximum stress the shale will be confined by a monolith which will rise from the sandstone below the shale. The maximum stress for this condition will be about 35 lb per sq in., giving a factor of safety of about 7.6.

Laboratory tests and computations thus confirm the geological conclusions as to the competency of the shale to support the load of the dam. There are factors, however, which the laboratory tests and computations cannot take into consideration but which are included in the demonstration given by the canyon walls. The shale is intersected by cracks and planes of weakness along which the resistance to shearing is less. If only the laboratory results were considered there would remain the possibility that these fractures might so weaken the shale that it might fail under the increased load. The canyon walls, however, demonstrate that the shale is actually standing a similar or greater load without evidence of failure. Therefore, the field and laboratory methods together give greater assurance than either alone. The laboratory method gives definite values for certain cases and the field observations take into consideration factors that cannot be provided for in the laboratory. The conclusion must be, therefore, that the shale will not fail under the additional load to be imposed by the dam.

Another problem is caused by the cracking of the shale upon drying and its disintegration when wet again. Drying and disintegration of the shale proceed rapidly. Exposure of a few hours causes the formation of cracks, and every crack expedites drying by letting air into the mass of the shale. When the shale is again exposed to water it slakes and disintegrates rapidly to mud. As a result there are no natural exposures of shale, unless they have been formed very recently by the cutting of a stream, or otherwise. Where the red shale outcrops in the canyon wall the solid shale is concealed by many feet of cracked shale and chips.

Due to this rapid drying and disintegration of the shale it must be protected during excavation for foundations either by leaving several feet of shale in place until ready to pour concrete and then making the final excavation and placing concrete rapidly, or by painting the surface of the shale with an asphaltic or other protective preparation. The only places where this problem is important are at the two abutments where concrete is poured against vertical faces of shale, and the dam is stepped up from the lower sandstone to the canyon sandstone.

In order to avoid having any part of the dam rest directly upon the shale it was necessary to cut vertical faces in the shale which is 70 ft thick on the north side and 50 ft thick on the south side. On the south side the shale supports a load of cap rock 80 ft thick but on the north side the cap rock is only 20 ft thick. There was fear that on the south side a vertical face might not stand up under the heavy load of cap rock. To avoid the necessity of an unsupported face of shale at the south abutment, columns of reinforced concrete were constructed, extending from the sandstone below the shale to the canyon sandstone above the shale. These columns were designed to act as beams to give lateral support to the shale. Shafts were sunk in the shale under the edge of the cap rock, and concrete was poured in these shafts. Before the shale was excavated, a monolith 54 ft away had been brought up to the level of the top of the shale and then the columns were braced against it. The shale was then excavated without difficulty, concrete panels were placed between the columns, and the monolith was poured[6] (see Fig. 4). This method was adopted before the

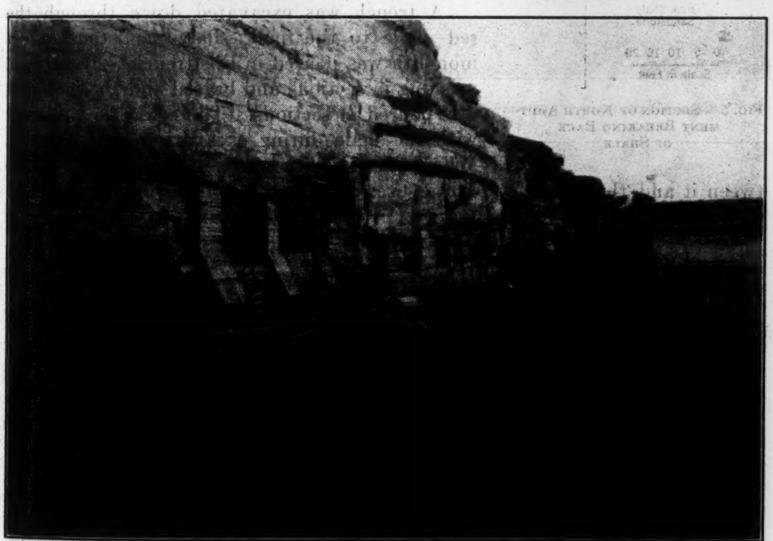

FIG. 4.—SOUTH ABUTMENT OF MAIN DAM, SHOWING SUPPORT OF SHALE, JANUARY 29, 1938

difficulties at the north abutment were encountered. This procedure was not considered feasible at the north abutment on account of the thinness and broken character of the cap rock. Since the load on the shale was much less here, an attempt was made to excavate a vertical face without any support and to pour the concrete against the shale; but when the face was about 50 ft high pieces of shale began to spall off and it was not safe to proceed. Spalling continued until the shale face had broken back an average of a few feet, with a maximum of 7 ft as determined by actual measurements from a skip suspended from the cableway. (See Figs. 5, 6, and 7.) The cap rock did not collapse and was left overhanging. The face remained in that condition for three months, until it was cut back. Several plans were studied and one was adopted which not only removed all question as to the stability of the shale face but solved other difficulties as well.

---

[6] For more complete description see "Dam Building on Difficult Rock," *Engineering News-Record*, June 9, 1938, p. 810.

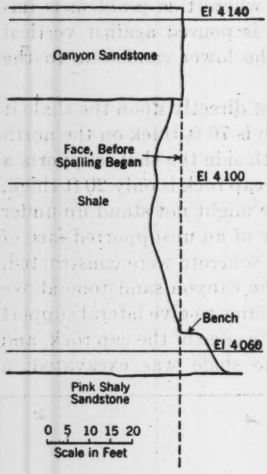

FIG. 5.—SECTION OF NORTH ABUTMENT BREAKING BACK OF SHALE

A trench was excavated down through the red shale to the pink shaly sandstone and a monolith was poured in this trench. The trench was dug in sections and braced and the monolith was poured in sections. There was no difficulty with the shale during excavation of the trench. When the monolith was complete, the shale between it and the exposed face was excavated and the intervening monoliths were poured.

PRACTICAL PROBLEMS OF THE ARTESIAN SANDSTONE AND THE PINK SHALY SANDSTONE

The artesian sandstone forms the foundations of the highest part of the dam and is a good rock for this purpose. It is moderately strong, its compressive strength as shown by eight tests ranging from 6 500 to more than 10 650 lb per sq in. There are problems, however, due to the fact that it is porous, is intersected by joint cracks, and contains water under artesian pressure.

The artesian sandstone was not exposed before excavations were begun, but it was investigated by numerous core borings and by two 30-in. borings, 76 and 81 ft deep, respectively, into which it was possible to descend and inspect the rock. Such large borings are the most satisfactory means of investigating foundation rocks. The smoothly cut surface of the holes shows up cracks, seams, and soft layers to much better advantage than the rough sides of shafts.

When the first holes were drilled into the artesian sandstone water flowed from them. The largest artesian flows were from the middle part of the upper artesian sandstone and from the lower artesian sandstone. The static head of water in the various holes was measured. The elevation of the river at the dam site is approximately 4 050 ft and the highest static head of water in the

FIG. 6.—NORTH ABUTMENT BEFORE SPALLING OF SHALE, SHOWING ASPHALTIC COATING

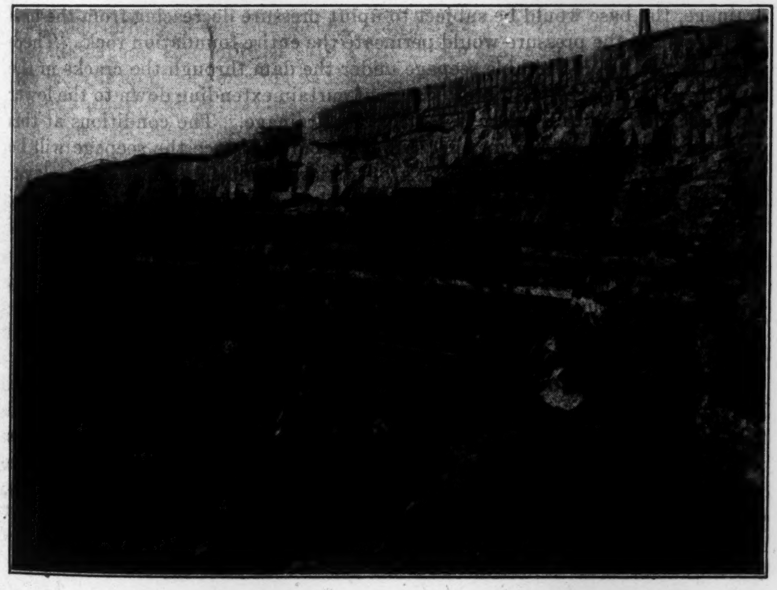

FIG. 7.—NORTH ABUTMENT AFTER SPALLING OF SHALE, SHOWING OVERHANGING SANDSTONE CAP ROCK

holes which penetrated the upper artesian sandstone only was 4 065 ft. The upper artesian sandstone outcrops in the South Canadian River two miles up stream from the dam at approximately the same elevation. The lower artesian sandstone outcrops farther up the river at a somewhat higher elevation and the highest static head of artesian water in holes penetrating the lower sandstone is 4 082 ft. Both these static heads agree with the elevations of the probable intake areas of the upper and lower artesian sandstones. Therefore, when the reservoir is full the water in these sandstones will be subject to the effect of this head.

The percentage of voids in the central part of the upper artesian sandstone varied from 6.4 to 22.7. The porosity of the upper 30 ft is comparatively low, and for the lower part, next to the lower red shale, it is also low. The permeability of the sandstone was tested both parallel and perpendicular to the bedding. The permeability parallel to the bedding is greater than it is perpendicular to the bedding, but even so it is low. The highest coefficient of permeability measured was 1.2 by 10^{-5} cm per sec. At this permeability water would flow through the sandstone under unit hydraulic gradient at the rate of 0.000024 ft per min. This is only 0.037 ft per day, an extremely slow flow, which could not account for a flow of 121 gal per min from some of the holes. This fact and others indicate that the artesian water moves principally through cracks rather than through the pores of the rock. Observations in the two 30-in. borings support this conclusion. Since the rock is porous and permeable, artesian pressure under static conditions will be equalized throughout it.

If the dam were built on this sandstone without a grout curtain and without drainage, the base would be subject to uplift pressure decreasing from the heel to the toe and the pressure would permeate the entire foundation rock. There might also be an undesirable seepage under the dam through the cracks in the sandstone. Seepage is reduced by a grout curtain extending down to the lower red shale, and uplift pressure is reduced by drainage. The conditions at this dam site are excellent for an effective grout curtain since the seepage will be principally through cracks, and the grout holes can reach an impervious layer at a moderate depth. Since seepage will be through cracks which are generally vertical, inclined holes are more effective in intersecting the greatest number of cracks.

The grout curtain consists of holes on 4-ft centers at the heel of the dam, dipping 75° S—that is, inclined 15° from the vertical. Every other hole extends down into the lower red shale and the alternate holes reach a vertical depth of 20 ft. Provision was made for closer grouting where necessary.

In rock with flat bedding seams, there is danger of opening the seams and lifting the rock by excessive grout pressure. Such uplift has been observed in some cases and since open bedding cracks were seen in the two large borings the possibility of this uplift was eliminated by restricting the pressure to the weight of the overlying material. Grouting was done after considerable concrete was poured and grout pressure was restricted to 1 lb per sq in. per ft of overlying rock and concrete. In order to use higher pressures in the lower part of the holes they were grouted in stages using stops at a vertical depth of 20 ft.

The average grout consumption of 122 deep holes was 62.9 sacks, the minimum, 0.1 sack, and the maximum, 3 683 sacks. The average per foot of hole was 1.05 sack. Omitting the 2 holes that required more than 600 sacks each the average is 24.9 sacks per hole, or 0.42 sack per ft of hole. The average grout consumption of 111 shallow holes was 15.5 sacks, the minimum was 0.1 sack, and the maximum was 433.2 sacks. The average per foot of hole was 0.78 sack. Subsequent boring has produced cores with cracks thoroughly filled and two parts of the core firmly cemented together. In addition to the line of grout holes at the heel of the dam, provision is made for a line of holes from a gallery in the dam. These holes can be grouted at higher pressures after the dam is completed. At the abutments where the foundation is stepped up to the canyon sandstone the grout holes were inclined under the cliff and higher pressures were used.

Relief of uplift pressure is provided by a line of 8-in. drain holes from a gallery down stream from the grouting gallery. The average spacing of drain holes approximated 15 ft on centers. They were drilled to the red shale after all grouting had been completed. This program of grouting and drainage should solve the practical problems of the artesian sandstone. The drain holes will relieve uplift pressure and the grout curtain will prevent undesirable seepage.

Artesian aquifers similar to this sandstone are believed to be subject to compression under increased load and to expansion under increased artesian pressure.[7] Since the artesian sandstone will be exposed to reservoir water it will be subject to the fluctuating head of the reservoir and, theoretically, it should expand and contract. It is not known that any such movement has been recognized at any existing dam and it would probably affect a considerable area uniformly and be harmless. Further research on this point is desirable.

As has been mentioned there are lenticular shaly beds in the upper part of the upper artesian sandstone. These beds are not continuous and, therefore, the foundations of the different monoliths were excavated to different depths in order to reach beds of massive sandstone.

On either side of the river near the abutments it was not considered necessary to go down to the artesian sandstone and the foundations were placed on massive beds in the pink shaly sandstone formation. The only possible danger from this rock is in regard to sliding on some of the shaly bedding seams, but the excavations were carried down to such depth that sliding would involve shearing overlying beds of massive sandstone, which would be practically impossible. Unconfined compressive tests on the pink shaly sandstone showed a minimum strength of 2 240 lb per sq in. when wet, and a maximum of 6 940 when dry. Shear tests parallel to the bedding on typical samples in natural condition under a transverse load of 100 lb per sq in. gave a minimum strength of 441 lb per sq in., a maximum of 2 035 lb, and an average of 971 lb per sq in.

---

[7] "Compressibility and Elasticity of Artesian Aquifers," by Oscar Edward Meinzer, *Economic Geology*, Vol. 23, No. 3, 1928, pp. 263–291.

It is believed that the foundation beds selected in both the artesian sandstone and the pink shaly sandstone are thoroughly competent to support the loads imposed upon them.

STABILITY AND TIGHTNESS OF THE CANYON SANDSTONE

The canyon sandstone at the north abutement was cut by many open cracks, and large blocks near the edge appeared to have moved. Therefore, questions were put to the geologist as to the cause of these cracks and their open condition, as to the cause of the movement of large blocks of sandstone, whether this movement would continue after the dam was built, and as to whether this rock was a satisfactory foundation for a dam 100 ft high. Furthermore, there was the problem of preventing seepage through cracks in the sandstone.

Most of the cracks in the sandstone are clearly joint cracks such as intersect the sandstones throughout this region. The two possible causes of opening of the cracks are solution and movement of the blocks. This sandstone is somewhat calcareous and in places shows signs of solution, but most of the cracks are free from such evidence. On the other hand it is obvious that many of the blocks near the canyon wall have moved, and since open cracks are restricted to the vicinity of the canyon, movement of the blocks is obviously the explanation. The cause of this movement is due partly to undermining by weathering and disintegration of the shale and partly to frost action and expansion from temperature changes. The blocks would move easily toward the canyon wall and there would be little tendency for them to move back.

The high part of the dam is extended back some distance from the canyon wall at the north abutment, resulting in the removal of the sandstone cap near the canyon with the consequent removal of all blocks that have moved. The problem, therefore, is to prevent future movement. When the dam is completed the outcrop of red shale in the canyon walls will be covered by an earth enbankment which will effectively prevent weathering of the shale near the dam and will thus prevent undermining of the sandstone. The earth embankment of the wing-dams will cover the surface of the sandstone to the canyon wall and will thus protect the sandstone from frost action and temperature changes. Therefore, the causes of movement of sandstone blocks will have been removed when the dam is completed, and there should be no future tendency for the blocks of the cap rock under or near the dam to move. Thus, by analysis of the causes of the unfavorable conditions, it was possible to remedy these conditions, prevent their future recurrence, and obtain assurance that the foundations will remain stable.

The canyon sandstone is a moderately strong rock, as is shown by the unconfined compression tests on six samples under different conditions, presented in Table 3. This formation varies from a hard massive sandstone to a softer thin-bedded sandstone, and the lower values were from samples of the softer sandstone.

From a foundation viewpoint the sandstone cannot be considered alone because it rests upon the red shale which is a much weaker rock. It has been shown that the red shale is strong enough to support the load of the dam but that there may be a total maximum settlement of 4 in. over a period of years. There may also be some adjustment due to plastic flow of the shale. The amount of settlement is not as important as its character (that is, whether it is irregular or even), and the way it is transmitted by the sandstone to the dam.

TABLE 3.—COMPRESSIVE STRENGTH OF CANYON SANDSTONE, IN POUNDS PER SQUARE INCH

Position, in respect to bedding	Strength of Sample Nos.:										
	1		2		3		4		5	8	
	Dry	Wet	Dry	Wet	Dry	Wet	Dry	Wet	Dry	Dry	Wet
Perpendicular	7 870	7 850	8 220	7 220	2 820	2 590	8 500	7 820	5 740	3 200	2 610
Parallel	8 550	7 030	4 130	4 070	2 310	2 150	7 670	6 410	8 120	6 020	3 280
45°	5 100	4 700	4 200	3 820	4 150	3 470	8 210	4 150	....	....	....

If the sandstone were a continuous, unbroken bed it would distribute any settlement effectively, but actually it consists of several beds intersected by numerous joint cracks. Since the cracks are offset from bed to bed, it may be likened to a mass of dry masonry with offset joints. It will thus be more effective in spreading the load than if the joints continued directly through all the beds, but less effective than an unbroken bed. The sandstone cap in the north abutment is only about 20 ft thick whereas at the south abutment it is about 80 ft thick, and, therefore, will spread the load much more effectively than at the north abutment. This was one reason for extending the high part of the dam farther back from the canyon wall at the north abutment. There will probably be some small uneven settlement of the different monoliths of the dam at the north abutment but provision has been made for it. The conclusion reached was that the canyon sandstone would provide satisfactory foundations for the dam.

There remains the problem of preventing seepage through the cracks of the sandstone. This is especially important because such seepage might tend to erode the top of the red shale. Consolidation grouting of the canyon sandstone to fill the cracks was required for the entire area of the concrete and earth dams; then a grout curtain was formed at the heel of the concrete dam by a line of inclined holes extending down to the red shale. This grouting was done after at least 25 ft of concrete had been placed, and grout pressures were restricted to 1 lb per sq in. per ft of overlying materials. Fifty-four shallow holes, each 20 ft deep, required 2.32 sacks of cement per foot, an average of 46.4 sacks per hole. The maximum was 935 sacks and the minimum was 0.0 sacks per hole. Twenty-six deep holes, averaging 7 ft, required 1.99 sacks per foot of hole or 77.4 sacks per hole. A comparison of inclined and vertical holes proves the greater effectiveness of the former. Thirteen deep inclined holes averaged 3.84 sacks per foot of hole, whereas ten vertical holes averaged only 0.31 sack per foot of hole. The permeability of the sandstone is very low, the highest coefficient of permeability found being 2.8 by 10^{-5} cm per sec, or 0.000056 ft per min. This is comparable with the artesian sandstone, and seepage through the unfractured rock will be negligible. Since seepage will be through cracks and not through the pores, grouting should prevent seepage, effectively, through the canyon sandstone under the dam.

CONCLUSIONS

The foregoing description of Conchas Dam illustrates the problems of constructing a high concrete dam on a soft, weak shale, or siltstone. Such rocks are common in the Southwest and similar problems occur in other regions; but high concrete gravity dams on such foundations are rare. There are certain similarities between the foundation problems of Conchas Dam and Tygart Dam on the Tygart River, near Grafton, W. Va. The fire-clay shale, or indurated clay at Tygart Dam, is not laminated and is somewhat similar to the red shale at Conchas Dam; but it occurs in thinner beds separated by beds of strong sandstone, and the practical problems are less serious. The same is true of the State Line or Lake Lynn Dam, on the Cheat River, in West Virginia, which has been in use for more than ten years.

The investigation of the foundations of Conchas Dam has involved extensive geological field studies, not restricted to the immediate dam site, an extensive drilling program, large drill holes, tunnels and test shafts, physical, and chemical tests, and tests adapted from soil mechanics; but, nevertheless, it has been essentially a geological investigation, using every means available to solve geological problems. Where precise laboratory methods could be used it was necessary to apply their results to the conditions in the ground, and it was realized that conclusions from the precise tests could be no more accurate than the geological interpretation of conditions in the ground to which they were applied. The application of precise methods to geological data, which from their very nature cannot be expressed in terms of precise measurement, involves the exercise of judgment lest the seemingly precise solution by laboratory methods of parts of the problem may seem to indicate that the solution of the entire problem is precise. Such a conclusion would lead to unwarranted confidence and might result in disaster.

Since at practically no dam site is it possible to obtain all the desirable information, the importance of geological judgment and familiarity with similar sites becomes clear. Great care must be exercised, however, so that "judgment" will not be carried to the dangerous extreme of assuming that, because a site is similar to another site, a similar dam will result in similar satisfactory results. The only safe course, therefore, is to obtain all the information possible, use the best precise methods applicable, compare details with similar details elsewhere, use the best geological judgment, and then provide for the worst possible conditions. The last provision will take care of the impossibility of obtaining all desirable information and the use of judgment based on experience will obviate resort to unnecessarily expensive designs.

The geological investigation of Conchas Dam site has emphasized the need of additional research upon several problems. A better understanding is desirable of the compaction of shale, and additional high-pressure "consolidation" tests on shales where the former load on them can be estimated should give valuable results.

Little is known about the slow plastic flow or creep of shale under pressures less than its shearing strength over a period of years, although there are many indications that such movement does take place. Laboratory tests, field tests on construction jobs, and systematic observations over a period of years on completed structures should give important information. Laboratory tests such as placing a specimen of shale under a constant load less than its shearing strength for months, and having provision for measuring shortening and lateral expansion of the specimen, should prove whether there is a slow deformation under moderate load. It is essential, however, to protect the specimen from drying during testing. If the elevation of a dam on uncemented shale were checked for a period of years against a datum well removed from the influence of the dam, and settlement of the dam were checked against the expected settlement as computed from consolidation tests, there would be an indication as to whether movement other than compaction were taking place in the shale.

It is known that artesian aquifers will expand when subject to artesian pressure and contract when that pressure is removed, but there is practically no information as to whether dams underlain by an artesian aquifer are subject to appreciable movement. Long-continued observations on dams, such as Conchas Dam, which rest upon an artesian aquifer that will be exposed to the fluctuating head of a flood control reservoir, should give valuable information. It would be necessary to refer the observations to a datum well down stream from the dam.

The problems of Conchas Dam are typical of those to be encountered with sites on the extensive red beds and similar formations. Since the most difficult problems—those concerned with settlement and plastic flow—may occur wherever uncemented shales occur, and since such formations are found throughout a vast area of the Southwestern, Western, and Northwestern plains, Conchas Dam illustrates some of the most important foundation problems of innumerable dam sites.

DISCUSSION

H. L. JOHNSON,[8] ESQ. (by letter).—The geological conditions at Conchas Dam and the major problems resulting from them, are presented in this excellent paper. The author demonstrates the application of geological knowledge to foundation and allied engineering problems. Mr. Crosby states (see heading "Geology of the Dam Site") that, in the upper red shale, the percentage of clay sizes and voids is higher in the south abutment than in the north abutment. This condition was indicated by the initial and incomplete tests run on the shales from both abutments; but a study of the complete data from all tests run on the shales indicates that the average composition and physical characteristics of the red shale in the north and in the south abutments are identical for all practical purposes. The average results for voids and density on a total of 114 samples are presented as Items 1 and 2 in Table 4. The voids in all samples were completely saturated. The average results of grain size determinations on a total of fifty-eight samples, with respect to clay sizes, are given in Item 3, Table 4.

TABLE 4.—CHARACTERISTICS OF RED SHALE

Item No.	Description	South abutment	North abutment
1	Percentage of voids	24.93	24.11
2	Density, in pounds per cubic foot	146.88	147.33
3	Clay sizes (percentages)	37.04	38.05

The author is correct in stating that the red shale is unstratified and that the proportions of grain sizes vary considerably from place to place, as do other characteristics of the shale. It is important to note that this variation is not regular, either horizontally or vertically, but is erratic in all directions. Thus, instead of regular zones, layers, or lenses of material having definite characteristics, the shale consists of irregular interlocked areas of varying characteristics which grade into each other without any definite line of demarcation other than an occasional color break.

The shear and compression values, used and cited by the author as a basis for determining the competency of the red shale, are confined to those obtained from two and three definite horizons in the south and north abutments, respectively. However, values actually used in determining the competency of the shale were representative of the full vertical and horizontal range of the shale at the abutments. In excavating the south and north abutments shale samples were taken, in so far as construction progress and facilities permitted, throughout the red shale exposed at the abutments so that the average characteristics could be determined for the full range of the material in question. In all, fifty-three shear tests and more than two hundred compression tests were made. In connection with the author's statement that, "The average shearing strength as computed from unconfined compression tests on twenty 2-in. cubes was 266 lb per sq in." (see heading "Practical Problems," following Case IV), it should be pointed out that all shear values entering into the design and stability computations were derived from direct shear tests on cylinders of shale 6 in. in diameter.

---

[8] Conchas Dam, N. Mex.

In the discussion of problems connected with the red shale Mr. Crosby refers to that part of the dam "resting upon the shale" and the parts of the dam "underlain by red shale." It should be made clear that no part of the Main Dam is founded directly on shale and that the entire dam is underlain by shale strata at depths of from 20 ft to 80 ft below the foundation sandstones. The terminal monoliths founded on the canyon sandstone are underlain by both the upper and lower red shales whereas the central monoliths, founded on pink shaly and artesian sandstone, are underlain by only the lower red shale.

That some settlement will occur because of the load of the dam and the presence of the underlying shales has been an accepted fact since the inception of the project. That there may be some differential settlement between those parts of the dam founded on the canyon sandstone and those founded on the artesian sandstone has been recognized and provided for in the design of the abutment monoliths. However, it is doubtful that the settlement differential will approach the 4 in. indicated by the author, whose computation is apparently based on the omission of the lower red shale from consideration or on the assumption that the lower red shale will be equally reconsolidated under the entire dam. This lower red shale has not been uniformly unloaded by erosion, that portion in the canyon being unloaded to a greater degree than those underlying the abutments or canyon walls. Hence, the degree of expansion due to erosional unloading (and, therefore, the resulting degree of reconsolidation possible in the lower red shale under the load imposed by the dam) must be greater in the canyon area than in the area underlying the canyon walls or abutments. Furthermore, the reconsolidation load imposed by the dam on the lower red shale will be much greater under the monoliths between the abutments, 200 to 235 ft high, than under the monoliths, 40 to 95 ft high, on top of the abutments. It is evident, therefore, that although the total thickness of shale underlying the high monoliths is only slightly more than one-third of the total that underlies the abutments it will unquestionably undergo materially greater reconsolidation. Thus the lower red shale is an important factor because it will tend to act as an equalizer of settlement between the high and low parts of the dam.

In addition to the construction problems involved in excavating the abutment faces in the upper red shale and constructing the abutting monoliths, there was also the problem of insuring a water-tight joint between the upper red shale and the adjacent monoliths. This problem arises from the fact that the shale shrinks appreciably upon exposure to air, with a resultant loss of moisture content. This drying and shrinking produces innumerable hair cracks and causes the opening of the old planes of movement (slickensided fracture planes) which traverse the shale in all directions and frequently are of considerable extent. Every effort was made to prevent drying of the shale by spraying it with a bituminous sealing compound as soon as possible after exposure. However, experience has shown that this treatment is not wholly effective and some drying and shrinkage, with the resultant development of cracks and opening of old fractures, is unavoidable. These cracks, especially those resulting from the opening of old fracture planes, are more or less inter-connected and provide a possible path of leakage around the abutments. In addition to the shale problem there was also the possibility that some differential settlement would occur between the abutments and the abutting monoliths and that shrinkage in the concrete of the abutting monoliths would tend to open the abutment joints. These conditions precluded the use of the conventional copper waterstops and indicated the need of a special material for grouting the shale and for use as waterstops, which would remain plastic and have the ability to come and go with any movement between the abutments and abutting monoliths. Three vertical sealing wells were installed, therefore, along and astraddle of each abutment joint. They were 15 in. in diameter, the two outside wells at each abutment being filled with an internal set-up bituminous material whereas the center well was filled with a mixture of sand and bentonite. At the south abutment the vertical joint between the shale and concrete, as well as the shale itself, was grouted with an internal set bituminous material that was mixed and pumped cold. This material possesses the property of setting up internally, several hours after mixing and injecting, to produce a plastic rubbery product. The shale was grouted with bitumen after the abutting monolith was constructed, the grout being injected by means of a system of piping embedded in the abutting monoliths during construction. Provision has been made for similar grouting at the north abutment should it become necessary.

In discussing the problems of the artesian sandstone upon which most of the high monoliths between the abutments are founded and which underlies the remainder of the dam at varying depths, the author states: "If the dam were built on this sandstone without a grout curtain and without drainage, the base would be subject to uplift pressure decreasing from the heel to the toe ***" (see heading "Practical Problems of the Artesian Sandstone and the Pink Shaly Sandstone"). This statement is obviously true of any gravity dam regardless of the kind and type of foundation material, unless the foundation materials were absolutely impermeable. The presence in the foundation of an artesian sandstone which outcrops or has intakes within the reservoir does give rise to an unusual uplift problem. With geological conditions, particularly those of artesian nature which occur at Conchas Dam, it is apparent that: (1) A grout curtain along the heel of the dam is wholly ineffective so far as uplift due to artesian pressure is concerned; and (2) without artificial drainage of the artesian aquifer at the dam, and in the absence of a natural outlet, the artesian uplift will be essentially uniform throughout the entire foundation area and will be equal to the hydrostatic head between pool level and foundation level. To relieve artesian uplift throughout the foundation area sixty-six 8-in. drain holes were drilled into the foundation, as mentioned by the author, at approximately 15-ft centers along the center line of the operating gallery, which is situated approximately 50 ft down stream of the grout curtain at the heel. These holes penetrate the upper artesian sandstone to within 2 to 5 ft of the underlying lower red shale. These drain holes and an inter-connecting tile and gravel drain laid upon the foundation will also serve to dispose of reservoir water passing the grout curtain at the heel of the dam, and will reduce uplift pressure resulting from it.

That artesian aquifers are compressible and elastic to varying degrees, dependent on the kind of rock or material comprising the aquifer, is known and generally accepted by authorities on ground water.[9] However, the nature of this phenomenon is such that any expansion or contraction, due to fluctuations in the artesian head resulting from variations in pool level in the artesian sandstone underlying Conchas Dam, should be fairly uniform throughout the area of the dam. The drainage system previously discussed will also be instrumental in reducing (if it does not wholly prevent) any tendency of the artesian aquifer to expand or contract by maintaining the artesian pressure under the dam at a uniform head.

In addition to the grout curtain which is continuous from the southeast end of the South Wing Dam, through the Main Dam, to the north end of the North Wing Dam, there was an extensive program of consolidation grouting in the canyon sandstone abutments. In this program every joint or crack of any appreciable size, exposed in the foundations or abutments, was cleaned out by washing and tapped with pipes to permit consolidation grouting after sufficient concrete or fill had been placed to permit the use of effective grouting pressures. Consolidation grouting was performed, whenever possible, in advance of the drilling and grouting of the grout curtain, in order that the cores obtained from the holes of the grout curtain might serve as a check on the effectiveness of the grouting. In addition to the consolidation grouting at the south abutment the vertical face of the canyon sandstone receives a protective coating of gunite for a distance of approximately 125 ft up stream from the dam. This is the only area adjacent to the dam where the highly jointed canyon sandstone is not to be covered by back-fill and would be exposed to the waters of the reservoir. In the remainder of the up-stream areas adjacent to the abutments the canyon sandstone, and the upper red shale, are protected from weathering, and the path of any possible seepage is lengthened in a somewhat unusual manner by virtue of extensive impervious back-fills. These back-fills extend approximately 160 ft up stream along the abutments from the dam and are themselves protected by pervious and rock-fill blankets.

In addition to past investigations of foundation conditions and allied problems, extensive preparations are being made to investigate: (1) The rate and distribution, as well as the ultimate future, of foundation settlement; (2) the quantitative effects of compressibility and elasticity of the artesian aquifer under operating conditions; (3) the deflection and tilting that will occur, and its relation to settlement; and (4), the effect of a full reservoir on artesian and ground-water conditions. To this end special equipment consisting of tiltmeters, plumb-bobs, underground bench-marks, and triangulation stations are installed in the Main Dam, and observations are made of artesian head at various core holes. The physical characteristics of the lower red shale are investigated by means of virgin samples obtained from several 8-in. drain holes which are extended into it. An extensive program of differential leveling and observing reference points set at the heel and toe of the various monoliths has been conducted continuously from October, 1937, to date (1939) in order to obtain foundation settlement data during construction.

---

[9] "Compressibility and Elasticity of Artesian Aquifers," by O. E. Meinzer, *Economic Geology*, Vol. 23, No. 3, May, 1928, pp. 263–291.

In closing this discussion the writer wishes to emphasize the fact that the difficulties and problems at Conchas Dam due to geological conditions were clearly recognized from the inception of the project and have been met by the continuous application of geological and engineering knowledge. Contributions to geological studies and to the solution of the various foundation problems at Conchas Dam have been made by E. G. Woodruff, who served as Geologist during the period of initial explorations; C. B. Theis, Associate Geologist, U. S. Geological Survey, Ground Water Division; W. M. Rau, Associate Geologist, U. S. Engineer Office, Little Rock, Ark., District; and the author. The writer has served as Foundation Engineer on the project since November, 1936.

IRVING B. CROSBY,[10] AFFILIATE, AM. SOC. C. E. (by letter).—Mr. Johnson has presented some additional data on the geological and foundation problems at Conchas Dam. He states that the conclusion that the percentage of voids was higher in the south abutment than in the north abutment was based upon initial and incomplete tests and that the complete data later available indicate that the physical characteristics of the shale in the south and north abutments are practically identical. However, the original tests cited in the paper were all that were available after investigation of the foundations had been under way for more than two years.

The writer stated, as information from official sources, that the average shearing strength of the red shale was determined from compression tests on twenty 2-in. cubes; but Mr. Johnson states that all shear values entering into the design and stability computations were derived from direct shear tests on cylinders of shale 6 in. in diameter. Since it is known that direct shear tests on shale give less reliable results than shearing values calculated from compression tests, the writer did not suppose that the results of the compression tests would be discarded at a late date in favor of results obtained by a less reliable method. The most accurate method of determining the shearing resistance of this shale would be by the triaxial compression tests.

In regard to possible settlement of that part of the dam underlain by red shale, the writer stated that consolidation tests had indicated that the maximum settlement under extreme conditions would be about 4 in. after a period of years. Mr. Johnson states: "However, it is doubtful that the settlement differential will approach the 4 in. indicated by the author, whose computation is apparently based on the omission of the lower red shale from consideration or on the assumption that the lower red shale will be equally reconsolidated under the entire dam." The writer did not omit the lower red shale from consideration, but the problem is extremely complicated. Certain facts essential for a rigorous solution were not obtainable, and simplification of the problem was necessary.

The formations at the dam site were laid down as flat beds in water and were buried by succeeding formations until there were at least 1 250 ft of sediments on top of the upper red shale. The lower red shale was buried approximately 150 ft deeper and had 1 400 ft of sediment on top of it. Therefore, other things being equal, the compaction of the two shales should vary as the loads upon them. About 1 225 ft of overlying rocks have been removed from above the upper red shale on the north abutment, reducing the load by 98% and allowing expansion of the shale. The dam on the north abutment will restore approximately 8% of this load and will cause some recompaction of the shale. In the canyon, erosion cut a maximum of 140 ft deeper, leaving only 70 ft of rock on the lower red shale and reducing the thickness of overlying rocks by 95 per cent. The highest part of the dam would restore about 18% of the original load. However, the lower red shale was unloaded only over a span of 300 ft, and it was covered by approximately 70 ft of strong artesian sandstone which would have some restraining effect. If the underlying shale had expanded appreciably, it should have uplifted the sandstone, with a tendency to open cracks in it. The fact that the sandstone contains water under artesian pressure indicates that the cracks have not been opened appreciably. Therefore, the amount of expansion and, consequently, the amount of possible recompaction of the lower red shale is uncertain. Since this shale is less than half as thick as the upper red shale, the possible settlement due to compaction of the lower red shale is less. Since undisturbed samples of the lower red shale were not available and, therefore, since it was impossible to estimate the compaction of this shale under a given load from a consolidation test, it was not possible to evaluate the settlement which might be caused by placing the dam on overlying rocks.

---

[10] Cons. Eng. Geologist, Boston, Mass.

It was desired, however, to estimate the effects of the worst possible conditions and, therefore, an estimate was made from consolidation tests of maximum possible settlement due to recompaction of the upper red shale from the load of the dam. The possible equalizing effect of differential recompaction of the lower red shale was disregarded purposely since it is uncertain and cannot be evaluated. It was realized that the estimates made gave an extreme value, probably considerably greater than could occur, as was stated in the writer's report, but that if the dam could be designed to meet this extreme condition it would be safe in any case. Since the dam could be designed to meet these extreme conditions without difficulty, this was done. An attempt to evaluate the uncertain effects of the lower red shale would not have made the dam any safer or have resulted in any important economy.

Mr. Johnson discusses the compressibility and elasticity of artesian aquifers without mentioning that these had been covered in the paper and that the conclusion had been reached that such movement would be uniform and harmless.

The special joint with sealing wells between the abutments and abutting monoliths is described in some detail by Mr. Johnson who thus supplements the paper on that subject referred to by the writer.[5] Mr. Johnson also gives additional information about the grouting program which was completed subsequent to the presentation of the paper. He also describes the most recent provisions made to study foundation settlement, and thus brings up to date (1939) the published information on Conchas Dam.

LATERAL SPILLWAY CHANNELS

By Thomas R. Camp,[1] M. Am. Soc. C. E.

With Discussion by Messrs. W. E. Howland, Lewis V. Carpenter and John K. Vennard and Fenner H. Whitley, F. Knapp, Carl Rohwer, Harold Allen Thomas, Jr., and Thomas R. Camp.

Synopsis

The term "lateral spillway channel" is used in this paper to designate an open channel which receives inflow throughout its length, laterally from one or both sides, and discharges the accumulated flow at a point in the channel, usually one end. When used for reservoir spillways, these channels are sometimes referred to as "side channel spillways." On a smaller scale they are found in all water and sewage treatment plants. The best known example is the "wash-water gutter" of rapid filter plants. Other examples are the main wash gutter or "gullet" of a rapid filter, effluent flumes or "launders" of settling basins, and the underdrains of trickling filters. The term "lateral spillway channel" is used herein in order to avoid confusion with "side weirs," with which the flow is in the reverse direction or from the channel over the weir.

In this paper, equations for the water-surface profile are derived for channels of constant width which receive their inflow uniformly throughout their length. The equations hold for both level and sloping inverts and for bottoms of any regular shape. A term is included to account for friction, and the equations are put in simple form and are accompanied by a graph to facilitate their use in design. Some experimental measurements are presented for the purpose of verifying the theory, and establishing the approximate value of the friction factor for channels used in water and sewage treatment plants.

Introduction

A number of attempts have been made to develop equations for the flow in wash-water gutters. Some of these equations were semi-rational, containing arbitrary coefficients. One equation failed to account satisfactorily for a sloping invert. Another equation was based upon the assumption that the water surface draw-down is equal to the velocity head. It has since been

---

Note.—Published in February, 1939, *Proceedings*.

[1] Associate Prof. of San. Eng., Mass. Inst. Tech., Cambridge, Mass.

shown,[2] and will be made evident in this paper, that the draw-down is much greater than the velocity head, even if friction is neglected.

Julian Hinds,[2] M. Am. Soc. C. E., in working with spillways for dams, was probably the first to make a substantially correct statement of the fundamental differential equation for the water-surface profile of lateral spillway channels. Mr. Hinds' theory is based upon the momentum principle. The differential equation is for the case in which the increment of inflow per unit of channel length is constant; and it is applicable to channels of any shape. The momentum of the inflowing water and friction in the channel are neglected in Mr. Hinds' equation. It is not readily integrable for the general case, and solutions are obtained by successive approximations dealing with short lengths of the channel. Friction losses are computed separately.

Mr. Hinds' differential equation was amended by Mr. Henry Favre[3] to include a friction term and to account for a component of inflow velocity in the direction of the axis of the channel. Mr. Favre integrated the equation for short lengths of the channel in which average values of the cross-sectional area and hydraulic radius could be used without introducing appreciable error. Solutions by means of Mr. Favre's equation require successive approximations with short channel lengths, as is the case with Mr. Hinds' equation, but the computations are probably expedited because of the presence in the equation of a term for friction.

For channels of variable or irregular shape, such as are required for the economical design of dam spillways, a general solution probably necessitates the use of the Hinds or the Favre method. In water and sewage treatment plants, however, lateral spillway channels are usually of constant width, with inverts having no slope, or a constant slope. For such structures a simplification of the equations and methods is both possible and desirable.

The differential equation developed in this paper is identical with that used by Mr. Favre, except that the friction term includes the well-known Weisbach-Darcy friction factor. Because of the simplicity of the channel shapes considered, it is possible to integrate the equation approximately so that it may be used for the entire channel without serious error. For accurate solutions, and for the determination of several points on the water-surface curve, successive approximations are required; but the procedure is much simplified.

FUNDAMENTAL DIFFERENTIAL EQUATION

For a steady state, the flow of water in a lateral spillway channel is not only non-uniform but is complicated by the fact that both velocity and discharge increase from zero at the up-stream end to maximum values at the down-stream end. In the following development, a constant increment of discharge is assumed per unit length of channel, and the momentum of the inflow is neglected. For a changing velocity, the momentum principle states that the accelerating force is equal to the time rate of change of linear momentum; or, that is, to the mass of water flowing times the acceleration produced.

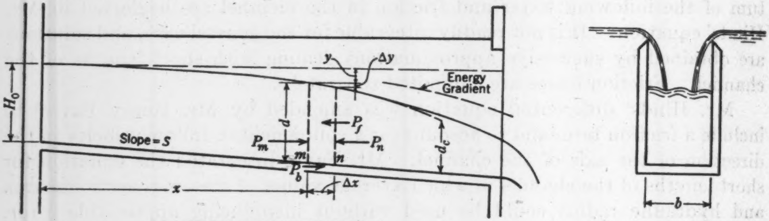
[3] *Engineering News-Record*, October 25, 1934, p. 520.

For a rectangular flume of width b (Fig. 1), consider two vertical cross-sections at Sections m and n, a distance Δx apart. The momentum at Section m, for the mass per second, is

$$M_m = \frac{Q\,w\,V}{g} \qquad (1)$$

in which Q = the discharge at Section $m = q\,x$; q = the constant increment of inflow per unit length of flume; w = the unit weight of water; g = the



(a) LONGITUDINAL SECTION (b) CROSS SECTION

FIG. 1

acceleration of gravity; and V = the horizontal component of the mean velocity at Section m. The momentum at Section n for the mass per second is

$$M_n = \frac{(Q + q\,\Delta x)\,w\,(V + \Delta V)}{g} \qquad (2)$$

The change in momentum in the distance Δx is

$$\Delta M = \frac{w}{g}\,[Q\,\Delta V + q\,\Delta x\,(V + \Delta V)] \qquad (3)$$

or, neglecting the product $\Delta x\,\Delta V$ and expressing Equation (3) in terms of differentials,

$$dM = \frac{w}{g}\,[Q\,dV + q\,V\,dx] \qquad (4)$$

Since $\dfrac{dM}{dt} = \dfrac{dM}{dx}\,\dfrac{dx}{dt} = V\,\dfrac{dM}{dx}$,

$$\frac{dM}{dt} = \frac{w}{g}\left[V\,Q\,\frac{dV}{dx} + q\,V^2\right] \qquad (5)$$

in which dM is the change in momentum in the time dt.

Equation (5) gives the time rate of change of linear momentum at any section, m, for the mass of water flowing per second. This is equal to the net force in the direction of x producing the change. The net force in the direction of x acting upon the volume of water between Sections m and n is the difference between the static pressures less the friction force. The static pressure at Section m is

$$P_m = \frac{b\,w\,d^2}{2} \qquad (6)$$

and at Section *n* is

$$P_n = \frac{b\,w}{2}(d - \Delta y + S\,\Delta x)^2 = \frac{b\,w}{2}(d^2 - 2\,d\,\Delta y + 2\,d\,S\,\Delta x) \ldots\ldots (7)$$

in which S = the slope of the bottom. The horizontal component of the static pressure on the bottom is

$$P_b = b\,w\left(\frac{2\,d - \Delta y + S\,\Delta x}{2}\right)S\,\Delta x = w\,b\,d\,S\,\Delta x \ldots\ldots\ldots (8)$$

The net static pressure on the water prism *mn* is the summation of Equations (6), (7), and (8), or

$$P_m - P_n + P_b = w\,b\,d\,\Delta y \ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

It will be noted that the slope of the bottom has no effect upon the value of the net pressure. It may be shown also that a changing width b has no influence on the value of this force.

The friction drag is

$$P_F = F\,(b + 2\,d)\,\Delta x = \frac{F\,b\,d\,\Delta x}{R} \ldots\ldots\ldots\ldots\ldots (10)$$

in which F = the frictional drag per unit area of channel wall, and R = the hydraulic radius at Section *m*. The equivalent water head on the area *bd* corresponding to the friction drag P_F is:

$$\text{Head} = \frac{P_F}{w\,b\,d} = \frac{F\,b\,d}{w\,b\,d\,R}\,\Delta x = \frac{F}{w\,R}\,\Delta x \ldots\ldots\ldots\ldots (11a)$$

and from the Weisbach-Darcy formula this lost head is also given by

$$\text{Lost head} = \frac{f\,\Delta x\,V^2}{4\,R\,2\,g} \ldots\ldots\ldots\ldots\ldots\ldots (11b)$$

Hence, from Equations (11),

$$F = w\,\frac{f}{8\,g}\,V^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

in which f = the Weisbach-Darcy friction factor. From Equations (10) and (12),

$$P_F = \frac{w\,f\,V^2\,b\,d}{8\,g}\,\frac{}{R}\,\Delta x \ldots\ldots\ldots\ldots\ldots\ldots (13)$$

The net accelerating force on the water prism *mn*, from Equations (9) and (13),

$$\alpha_{mn} = w\,b\,d\,\Delta y - w\,\frac{f\,V^2}{8\,g}\,\frac{b\,d}{R}\,\Delta x \ldots\ldots\ldots\ldots (14)$$

and since the volume of water between Sections *m* and *n* is

$$b\,d\,\Delta x = \frac{\Delta x}{V}\,Q \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

the accelerating force on the water flowing per second (that is, Q) is

$$\frac{V}{\Delta x}\left(w\,b\,d\,\Delta y - w\,\frac{f\,V^2}{8\,g}\,\frac{b\,d}{R}\,\Delta x\right) = w\,Q\,\frac{\Delta y}{\Delta x} - w\,Q\,\frac{f\,V^2}{8\,g\,R} \quad \ldots\ldots (16)$$

Expressing Equation (16) in terms of differentials and equating to Equation (5):

$$\frac{dy}{dx} - \frac{f\,V^2}{8\,g\,R} = \frac{1}{g}\left[V\,\frac{dV}{dx} + q\,\frac{V^2}{Q}\right] \quad \ldots\ldots\ldots\ldots\ldots (17)$$

Equation (17) is general for any shape of channel, and it is identical with the Hinds equation except for the friction term.

Application to Constant Width Flumes

In order to integrate Equation (17) it is convenient to express the velocity, discharge and draw-down, y, in terms of the dimensions of the channel. For this purpose, $V = \frac{q\,x}{b\,d}$; $\frac{dV}{dx} = \frac{q}{b}\left[\frac{1}{d} - \frac{x}{d^2}\,\frac{dd}{dx}\right]$; and (since $y = H_0 + S\,x - d$), $\frac{dy}{dx} = S - \frac{dd}{dx}$. Substituting these values in Equation (17) and simplifying, the equation becomes

$$\frac{dd}{dx} = \frac{2\,q^2\,x\,d - S\,g\,b^2\,d^3 + \frac{f}{8\,R}\,q^2\,x^2\,d}{q^2\,x^2 - g\,b^2\,d^3} \quad \ldots\ldots\ldots\ldots (18)$$

Equation (18) may be written as follows:

$$\frac{2\,x\,d\,dx - x^2\,dd}{d^2} + \frac{g\,b^2}{q^2}\,d\,dd = \frac{S\,g\,b^2}{q^2}\,d\,dx - \frac{f\,x^2}{8\,R\,d}\,dx \quad \ldots\ldots (19)$$

The terms on the left side of Equation (19) integrate directly, and the partially integrated equation is as follows:

$$\frac{x^2}{d} + \frac{g\,b^2\,d^2}{2\,q^2} = \frac{S\,g\,b^2}{q^2}\int d\,dx - \frac{f}{8}\int \frac{x^2}{R\,d}\,dx + C \quad \ldots\ldots\ldots (20)$$

When $x = 0$, $d = H_0$, from which

$$C = \frac{g\,b^2\,H_0^2}{2\,q^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

In the term including S in Equation (20) the expression under the integral is equal to the area in the distance x between the water-surface curve and the bottom. This area equals $x\bar{d}$, in which $\bar{d}$ = the average depth throughout the distance x. An approximate integration of the friction term may also be had by assuming both R and d constant and equal, respectively, to $\bar{R}$ and $\bar{d}$, where $\bar{R}$ = the average hydraulic radius throughout the distance x. With these approximations, the completed integration is

$$\frac{x^2}{d} - \frac{g\,b^2}{2\,q^2}\left(H_0^2 - d^2\right) = \frac{S\,x\,g\,b^2\,\bar{d}}{q^2} - \frac{f\,x^3}{24\,\bar{R}\,\bar{d}} \quad \ldots\ldots\ldots (22)$$

Solving for H_0, Equation (22) becomes

$$H_0 = \sqrt{d^2 + \frac{2\,Q^2}{g\,b^2\,d} - 2\,S\,x\,\bar{d} + \frac{f\,x\,Q^2}{12\,g\,b^2\,\bar{R}\,\bar{d}}} \qquad (23)$$

Equation (23) may be used to solve for the value of H_0 if the value of d at any point in the channel is known or fixed. The solution requires, however, that the average values of R and d throughout the length considered be assumed for substitution in the equation. If the invert is level and the friction loss is small, the last two terms may be omitted. For an accurate solution of the value of H_0, after the first approximation is made, the equation must be solved for d at several points along the channel in order to check the assumed values of $\bar{R}$ and $\bar{d}$. Adjustments are then made by trial and error.

Equation (22) is a cubical equation in terms of d, and its solution for d is simplified if the equation is rearranged in dimensionless form as follows:

$$\left(\frac{d}{H_0}\right)^3 + \left(\frac{f\,Q^2\,x}{12\,g\,b^2\,\bar{R}\,\bar{d}\,H_0^2} - \frac{2\,S\,x\,\bar{d}}{H_0^2} - 1\right)\frac{d}{H_0} + \frac{2\,Q^2}{g\,b^2\,H_0^3} = 0 \qquad (24)$$

or,

$$\left(\frac{d}{H_0}\right)^3 + A\left(\frac{d}{H_0}\right) + B = 0 \qquad (25)$$

in which

$$B = \frac{2\,Q^2}{g\,b^2\,H_0^3} \qquad (26)$$

and

$$A = \frac{f\,H_0\,x\,B}{24\,\bar{R}\,\bar{d}} - \frac{2\,S\,x\,\bar{d}}{H_0^2} - 1 \qquad (27)$$

The solution of Equation (25) for $\frac{d}{H_0}$ may be obtained graphically from Fig. 2 for various values of A and B.

CRITICAL DEPTH

The flow characterized by the foregoing equations is at the upper alternate stage. For most of the lateral spillway channels used in water and sewage plants, the depth at the lower end of the channel will be fixed at upper stage by the hydraulic conditions in the conduit down stream, or the flume will discharge freely. In the latter case, illustrated in Fig. 1, the pressure distribution near the end of the flume will be non-hydrostatic due both to aeration under the nappe and to the existence of appreciable vertical acceleration in this region. The region will extend for a distance three or four times the depth up stream from the lower end. For the design of freely discharging flumes, a close approximation to actual conditions will be obtained if a hydrostatic control section is assumed to exist at a distance up stream from the end equal to three or four times the critical depth. Since the value of the critical depth for a rectangular flume is

$$d_c = \sqrt[3]{\frac{Q^2}{g\,b^2}} \qquad (28)$$

Equation (23) may be written in terms of the critical depth as follows:

$$H_0 = \sqrt{3\, d_c^2 - 2\, S\, x_c\, \bar{d} + \frac{f\, x_c\, d_c^3}{12\, \bar{R}\, \bar{d}}} \ldots\ldots\ldots\ldots \quad (29)$$

For this case, the coefficients in the cubical formula, Equation (25), have values as follows:

$$B_c = 2\left(\frac{d_c}{H_0}\right)^3 \ldots\ldots\ldots\ldots \quad (30)$$

and

$$A_c = -\sqrt[3]{\frac{27}{4}\, B_c^2} = -3\left(\frac{d_c}{H_0}\right)^2 \ldots\ldots\ldots\ldots \quad (31)$$

The value of B_c in Equation (30) was obtained by combining Equations (26) and (28) to eliminate $\frac{Q^2}{g\, b^2}$. The value of A_c in Equation (31) was obtained from Equation (25) by setting the derivative of B with respect to $\frac{d}{H_0}$ equal to zero and solving for A. Values of $\frac{d_c}{H_0}$ for various values of B_c or A_c are shown on the "critical depth" line of Fig. 2.

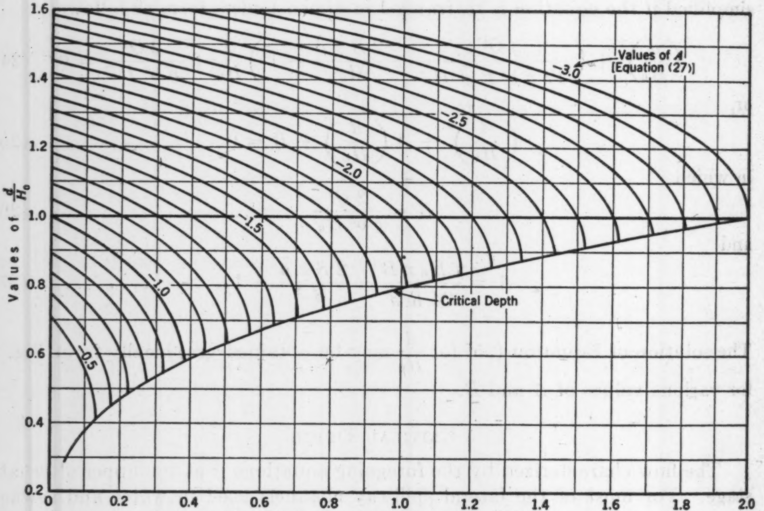


FIG. 2.—GRAPH FOR THE SOLUTION OF EQUATION (25)

CROSS-SECTIONS OTHER THAN RECTANGULAR

The foregoing equations were developed for rectangular cross-sections, but they are also applicable to channels with other bottom shapes if the depth at any section is taken as the average depth over the flume width. This may be demonstrated by consideration of Fig. 3 which shows a rectangular, a V-shaped and a semi-circular bottom. In all three cases, since the cross-sectional area is $b\,d$, the static pressure on the cross-section is

$$P = w\,b\,h_0\,d \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

in which h_0 = the depth to the center of gravity of the cross-section. The value of h_0, however, is not the same for the three cases.

For a rectangular cross-section, $h_0 = \frac{d}{2}$. For the V-shaped bottom,

$$h_0 = \frac{d}{2} + \frac{z^2}{6\,d} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

and,

$$P = \frac{w\,b\,d^2}{2} + \frac{w\,b\,z^2}{6} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

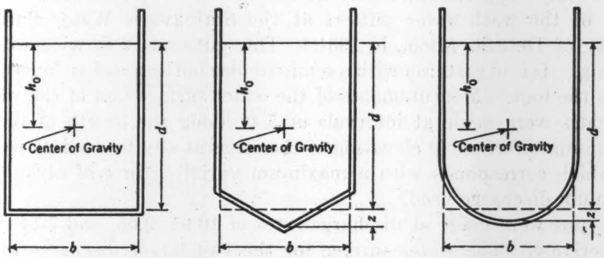

FIG. 3

The values of P_m and P_n are the same as those given by Equations (6) and (7) except that each contains the additional term $\frac{w\,b\,z^2}{6}$. The difference in pressures, therefore, is the same as for the rectangular flume and is given by Equation (9). For the semi-circular bottom,

$$z = \frac{4 - \pi}{8}\,b = 0.1073\,b \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35)$$

$$h_0 = \frac{d}{2} + \left(\frac{1}{12} - \frac{\pi^2}{128}\right)\frac{b^2}{d} = \frac{d}{2} + 0.0062\,\frac{b^2}{d} \ldots\ldots\ldots\ldots (36)$$

and

$$P = \frac{w\,b\,d^2}{2} + 0.0062\,w\,b^3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (37)$$

In this case, as in the case of the V-shaped bottom, the second term in the equation for P cancels when P_n is subtracted from P_m; and the net static pressure is given by Equation (9).

The critical depth is the same for any shape of bottom and is given by Equation (28), in which d_c is the average depth at the cross-section.

EXPERIMENTAL EVALUATION OF FRICTION FACTOR

Experimental measurements which are sufficiently complete and reliable for the evaluation of the friction factor are difficult to obtain. Since the theory is premised upon the assumption of a constant increment of inflow, it is imperative that the weir or weirs at the top of the flume walls be level. Moreover, because of the turbulence in the flume, an accurate measurement of the position of the water surface at any section is not possible. In order to counteract the effect of the errors in the measurement of the position of the water surface, the draw-down should be relatively great, and depth measurements should be made at three or more stations along the flume. The effects on the pressure distribution, of entrained air and of the momentum of the incoming water (both of which are of considerable importance for dam spillways), are negligible for the smaller channels used in water and sewage plants. The momentum of inflow results in increased friction factors due to increased turbulence.

The best set of experimental measurements available to the writer was made upon one of the wash-water gutters at the Springwells Water Purification Plant, City of Detroit, Mich., in 1931.[4] This gutter is 2 ft wide with weirs 40.25 ft long. It is of cast iron with a semi-circular bottom and an invert slope of 0.25 in. to the foot. Measurements of the water surface and of the weir crest on both sides were made at intervals of 5 ft along the length of the flume. The maximum difference in elevation of the weirs at any two points was about 0.01 ft, which corresponds with a maximum variation in q of about 15% at the maximum discharge used.

Three runs were made at discharge rates of 10.91, 9.05, and 7.14 cu ft per sec, respectively. The water surface for the two larger discharge rates was above the semi-circular bottom, so that b was constant along the flume. The friction factor was evaluated by means of Equation (23) at 0.055 for both of these runs. Fig. 4, with Table 1, shows the relative position of the measured water surface and of the profile computed by means of Equation (25) and Fig. 2.

Fig. 5, with Table 1, shows the measured and computed water surface curves for the central concrete gullets of one of the filters at each of the two water purification plants at Cleveland, Ohio. The measurements at the Division Avenue Plant were made in 1920, and at the Baldwin Filtration Plant in 1928, both sets being under the direction of G. W. Hamlin, M. Am. Soc. C. E. The values of f (0.10 and 0.11) obtained by these measurements on two different gutters of similar size tend to substantiate the reliability of both sets of measurements. The inflow to main gutters is at intervals along the length and not continuous, as called for by the theory. Notwithstanding this fact, these measurements indicate that the theory may be used with success for gullets in which the points of inflow are not too widely separated.

Measurements of the water surface at two points were also made in lateral gutters for the same runs. These gutters have weir lengths of about 15 ft at both plants. The computations for f in the lateral gutter at Division Avenue resulted in a negative value, doubtless due to the fact that the weirs were about

---

[4] *Transactions*, Am. Soc. C. E.. Vol. 101 (1936), Fig. 9, p. 362.

0.03 ft lower at the down-stream than at the upper end. The computed value of f for the lateral gutter at the Baldwin Plant was approximately 0.02 for a discharge of 4.42 cu ft per sec. This value is probably unreliable because it is based upon only two measured depths along the channel and because the condition of the weirs was not observed.

* Semi-circular bottom.

A number of experiments were run on a lateral spillway channel at the Massachusetts Institute of Technology under the direction of the writer.

This channel is of wood with rectangular cross-section, 9 in. wide, and with a level bottom. The inflow is from one side over a weir 20 ft long. Fig. 6 illustrates the results of one of the most reliable runs on this channel, made by

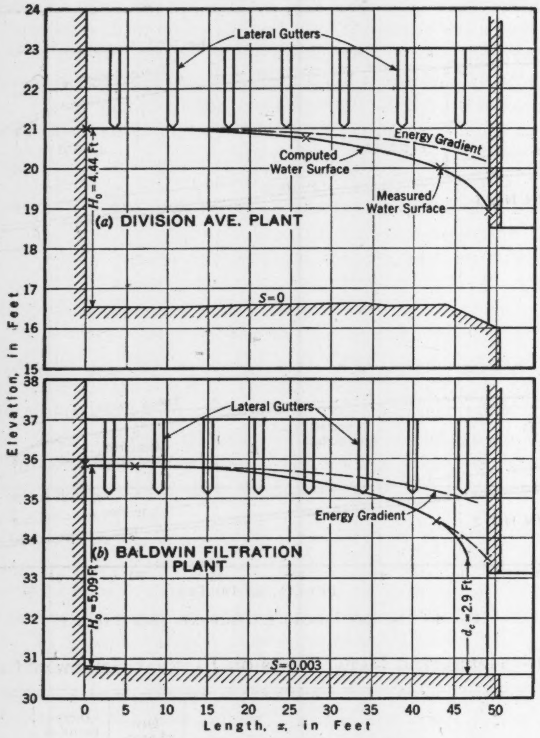

FIG. 5.—CLEVELAND (OHIO) EXPERIMENTS (SEE TABLE 1)

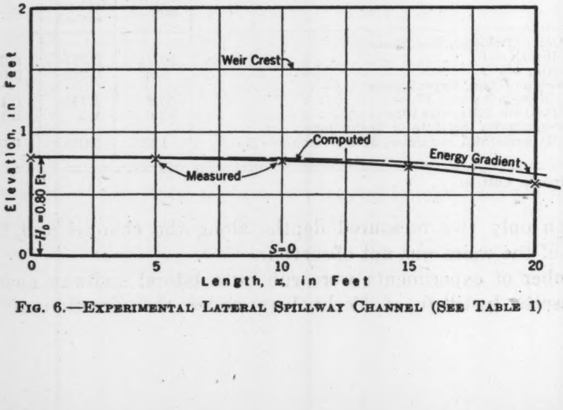

FIG. 6.—EXPERIMENTAL LATERAL SPILLWAY CHANNEL (SEE TABLE 1)

Mr. E. A. Kass.[5] The variation in level of the weir was only about 0.001 ft. The head on the weir was approximately 0.07 ft and the nappe fell freely. The computed value of *f* for this run was 0.033.

ACKNOWLEDGMENT

The writer is indebted to Mr. Hinds for the development of the basic differential equation which has been used in this paper. The experimental data from the Springwells Filter Plant in Detroit were furnished through the courtesy of Arthur B. Morrill, M. Am. Soc. C. E. The Cleveland data were furnished through the courtesy of J. W. Ellms, M. Am. Soc. C. E., and Mr. Hamlin. The writer also wishes to acknowledge the valuable assistance of a number of his students who made experimental investigations of flow and pressure characteristics.

[5] "Loss of Head in Lateral Spillway Channels," by E. A. Kass; presented to Massachusetts Institute of Technology in 1937, in partial fulfillment of the requirements for the degree of Bachelor of Science.

DISCUSSION

W. E. HOWLAND,[6] ASSOC. M. AM. SOC. C. E. (by letter).—The experimental data quoted in this paper clearly establish the validity of the basic differential equation used and the rational methods developed appear to the writer to be of great value in analyzing, completely, the behavior of lateral spillway channels. Because the integrated equations require adjustment by trial and error methods the writer has investigated the use of similar methods applied to the basic differential equation itself. Results indicate some value in this somewhat different method of approach.

Equation (17) may be rewritten as follows:

$$dy = \frac{1}{g}\left(\frac{f\,V^2\,dx}{8\,R} + 2\,V\,dV + \frac{dA}{A}\,V^2\right) \ldots\ldots\ldots\ldots (38)$$

since

$$q\,\frac{V^2}{Q} = \frac{dQ}{dx}\frac{V^2}{Q} = \frac{dQ}{dx}\frac{V^2}{A\,V} = \left(\frac{A\,dV + V\,dA}{dx}\right)\frac{V}{A} = \frac{V\,dV}{dx} + \frac{V^2}{dx}\frac{dA}{A} \ldots (39)$$

in which, in addition to the notation of the paper, A = area of cross-section of channel stream; otherwise symbols are those of the author. Equation (38) may be expressed as follows:

$$dy = 2\,d\left(\frac{V^2}{2\,g}\right) + 2\,\frac{V^2}{2\,g}\frac{dA}{A} + \frac{f}{4\,R}\frac{V^2}{2\,g}\,dx \ldots\ldots\ldots\ldots (40)$$

or, in words: The drop in the water surface between two sections a distance dx apart is twice the difference between the velocity heads of these sections, plus twice the product of the (average) velocity head in this length and the proportional change in area between the two sections, plus the allowance for friction head loss in this length between these sections.

An approximate method for calculating the difference in surface elevations along the channel might be to divide its entire length into a number of smaller lengths and then to apply Equation (40) to these separate lengths, treating the differentials that appear in the equation as actual assumed or calculated differences; thus:

$$\Delta y = 2\,\Delta\,\frac{V^2}{2\,g} + 2\,\frac{V_{av}^{\,2}}{2\,g}\frac{\Delta A}{A_{av}} + \frac{f}{4\,R}\frac{V_{av}^{\,2}}{2\,g}\,\Delta x \ldots\ldots\ldots\ldots (41)$$

in which V_{av} and A_{av} are average values of velocity and area. The burden of cutting and trying in applying Equation (41) progressively to a number of short sections of the channel, by the usual step method of calculation, has been found to be troublesome; nevertheless the equation has proved to be useful as will now be shown.

Calculations indicate that the first term to the right of the equation sign is of predominant importance in estimating the value of Δy (the vertical drop of water surface between sections). Thus, if the elevation of the water surface at the down-stream end of the channel is known, as well as the flows, the velocity head may be computed. Then the water-surface elevation at the upper end of the channel may be estimated approximately as two of these velocity heads higher than the down-stream water surface. This may be shown by a consideration of actual data in Table 2, obtained from the paper.

* Two velocity heads added to down-stream water-surface elevation.

The same principle may be used in the reverse direction; that is, assuming the elevation at the upper end of the section, the elevation at the lower end may be estimated in this manner:

$$\Delta y = H_0 + S\,x - d = 2\,\frac{V^2}{2\,g} = 2\,\frac{q^2\,x^2}{b^2\,d^2}\,2\,g \qquad \text{.............}(42)$$

Knowing H_0, S, x, q, b and g, one may solve Equation (42) for d. Using this formula to estimate the depth at a distance of 37.5 ft down stream from the upper end, in the Detroit plant tests, one obtains, in Run No. 1, $d = 1.04$ ft and in Run No. 2, $d = 0.87$ ft.

In the other experiments Equation (42) results in no real roots owing to the slight errors in the theory evident from Table 2; but a slight readjustment of the values of H_0 will yield equations with real roots.

These approximate calculations—based upon the assumption that the drop in the water surface between the up-stream end of the channel and any other point is twice the velocity head at that point—will probably be satisfactory for most practical purposes. They also serve as a basis for a more exact method for the analysis of the channels of this study. The writer proposes the following procedure for this purpose:

Laboratory Study to Obtain f.—In a laboratory study to obtain f, from measurements of the elevation of the water surface in the channel at a number of points (such as are indicated by Professor Camp) determine depths, areas and velocity heads at these sections and average velocity heads and substitute these and other dependent calculable values in Equation (41) and then compute f therefrom for each separate length of channel. No "cuts" and "trys" are needed in this procedure.

Exact Analysis.—In an exact analysis of a design, compute the water-surface elevations and depths at a number of sections along the channel by means of the approximation already considered. When the depth of channel is given at the down-stream section, first compute the elevation at the up-stream section as two velocity heads higher. (If the elevation at this section is assumed this step would not be necessary.) Then establish approximate depths at a number of sections below by means of Equation (42), assuming x and solving for d by trial or, if it is preferred, assuming d and solving for x. The latter procedure is more simple because it involves a quadratic instead of a cubic and does not require a cut and try solution. In Equation (42) all other quantities would be known, of course. Use this approximate water surface to compute the second and third terms on the right side of Equation (41) for the several lengths into which the channel has been divided (that is, the lengths between sections at which depths have been computed). Add, algebraically, both sets of "minor" terms; that is, obtain $\sum 2 \frac{V_{av}^2}{2g} \frac{\Delta A}{A} + \sum \frac{f}{4R} \frac{V_{av}^2}{2g} \Delta x$ for the entire channel and add this to the original estimate of Δy $\left(\text{that is, to } 2 \frac{V^2}{2g}\right)$ to obtain the more exact difference between water surfaces at the extremities of the channel. Thus H_0 may be recomputed. If desired, all the intermediate elevations may then be recalculated from the following modification of Equation (41):

$$H_0 + s\,x - d - \sum_0^x 2 \frac{V_{av}^2}{2g} \frac{\Delta A}{A} - \sum_0^x \frac{f}{4R} \frac{V_{av}^2}{2g} \Delta x = \frac{2\,q^2\,x^2}{b^2\,d^2\,2\,g} \quad \ldots (43)$$

The entire process could be repeated to obtain still greater precision starting with the newly determined water depths from Equation (43); but, since it appears (from Table 2) that very close approximations to the water surface were obtained with the first crude or simple approximation there is good reason to suppose that the foregoing procedure would yield satisfactory precision without repetition.

It is interesting to consider why the simple approximation (which neglects the second and third terms in Equation (41)) yields results which agree so well with measurements and with the results of more exact and elaborate methods of analysis. Apparently the reason is that these terms are of small value and tend to compensate each other. As given in Equation (41), the second term on the right side is predominately negative and the third is always positive. The second term would disappear absolutely if the bottom of the channel were parallel to the water surface, a condition which is approximated with inclined channels. This term becomes of greater importance as the channel is made more level, in which case it may more than compensate for the effect of friction (see the last two tests in Table 2). From the data given the friction term, itself, appears to be of very small importance, amounting to about 8% of the first term, in the first experiment quoted.

This study calls attention to the very considerable loss of energy which occurs in these channels due, not to friction, but to the impact of the slow moving, and fast moving, water. It suggests that an increase in capacity might result from the use of devices to deflect the incoming water into the direction of the main stream before it enters the stream. The writer would like to see tried the simple device of placing vanes, curved only in one direction (see Fig. 7). Such vanes might extend from the crests of the weirs down to the anticipated elevation of the water surface in the channel. It appears to be possible, theoretically, to increase the capacity of a channel as much as 50% by such energy-saving devices. Although the use of such devices might not be economical in an original design, it might be helpful in increasing the capacity of old channels that have proved to be somewhat inadequate.

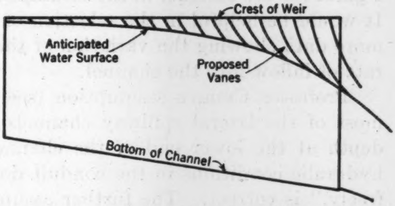

FIG. 7.—LONGITUDINAL CROSS-SECTION OF LATERAL SPILLWAY CHANNEL

To summarize: This study clearly establishes the validity of the basic differential equation employed. The writer suggests the use of the approximation—change in water-surface elevation in lateral spillway channels equals twice the difference in velocity heads between corresponding sections. This approximation may be used to advantage both for preliminary designs and also as the basis for exact analyses. Furthermore, the study emphasizes the great loss of energy that occurs from impact in these channels and suggests the possibility of improvements in design, to increase capacity.

LEWIS V. CARPENTER,[7] M. AM. SOC. C. E., JOHN K. VENNARD,[8] AND FENNER H. WHITLEY,[9] JUNIORS, AM. SOC. C. E. (by letter).—The problem treated in this paper has long been a vexing one for designers of certain types of sanitary engineering structures. The author is to be commended for the completeness of his solution. He has taken the well-known Hinds[2] analysis and adapted the equations so that they are available for the design of such appurtenances as wash-water gutters and trickling filter collection troughs.

The Weisbach-Darcy friction factor that Professor Camp uses in his mathematical analysis of flow is well known. As this friction factor is used in the equations of the paper, it is made to embody all of the various resistance phenomena that occur throughout the length of the channel. Resistance to flow in a lateral spillway channel comes from two fundamentally different sources: (1) That of skin friction at sides and bottom of the channel (which alone usually determines the size of f); and (2) that resulting from the interference of liquid entering the channel normal to its axis. Undoubtedly the latter effect is the predominant one in determining the size of the friction factor in lateral spillway channels. This fact is borne out by the trend in friction factors shown in Table 1 in which a channel having inflow over the entire length of only one side (M.I.T. tests) and having thus a minimum interference has the lowest friction factor (0.033). Where inflow is distributed over the entire length of the channel but enters from both sides (Detroit tests) a greater interference is produced and a greater friction factor (0.055) results. Where there is a concentrated inflow from lateral gutters (Cleveland tests) a maximum interference occurs and results in a still higher friction factor (0.10–0.11). Although the friction factor data in Table 1[9b] are meager, they indicate the effects of various types of inflow upon this factor, and thus provide a guide for the designer in the assumption of a friction factor for a given design. It would be helpful in the selection of values of f if the author could present more data showing the variation of the friction factor with a variation in the rate of inflow into the channel.

[7] Prof., San. Eng., Coll. of Eng., New York Univ., New York, N. Y.

[8] Asst. Prof., Fluid Mechanics, Coll. of Eng., New York Univ., New York, N. Y.

[9] Instr., San. Eng., Coll. of Eng., New York Univ., New York, N. Y.

Professor Camp's assumption (see heading "Critical Depth"), that "For most of the lateral spillway channels used in water and sewage plants, the depth at the lower end of the channel will be fixed at upper stage by the hydraulic conditions in the conduit down stream, or the flume will discharge freely," is correct. The further assumption that in the design of freely discharging flumes, a hydrostatic control section exists at a distance up stream from the end, equal to three or four times the critical depth, needs some qualifying statements.

Assume that in a rapid sand filter the lateral wash-water gutters are spaced 6 ft, center to center, and that they discharge freely. A vertical rise of 36 in. per min is used when washing the filter. The increment q will be 0.3 cu ft per sec per ft length of gutter, with one-half of the water coming in on each side. If the wash-water gutter is rectangular, the critical depth is given by Equation (28). In Table 3 the location of the hydrostatic control is calculated for lengths of 10, 20, and 40 ft and a breadth of gutter equal to 12, 15, 18, and 24 in., using the author's assumption. In the gutters at the Cleveland plant where the length is 49 ft, the author's assumption is fairly close because, at the hydrostatic control section, all of the water has entered the gutter.

TABLE 3.—EFFECT OF ASSUMING THAT THE HYDROSTATIC CONTROL SECTION IS UP STREAM FROM OUTLET AT A DISTANCE 3 TO 4 TIMES THE CRITICAL DEPTH

Length, l, in feet	Flow, Q, in cubic feet per second	Width, b, in inches	Depth, d_c, in feet	$3 \times d_c$, in feet	$4 \times d_c$, in feet	PERCENTAGE OF TOTAL Q NOT IN CHANNEL	
						Hydrostatic control up stream $3 \times d_c$	$4 \times d_c$
10	3.0	12	0.65	1.95	2.60	19.5	26.0
		15	0.56	1.68	2.24	16.8	22.4
		18	0.50	1.50	2.00	15.0	20.0
		24	0.41	1.23	1.64	12.3	16.4
20	6.0	12	1.04	3.12	4.16	15.6	20.8
		15	0.89	2.67	3.56	13.4	17.8
		18	0.79	2.37	3.16	11.9	15.8
		24	0.65	1.95	2.60	9.7	13.0
40	12.0	12	1.65	4.95	6.60	12.4	16.5
		15	1.42	4.26	5.68	10.7	14.2
		18	1.26	3.78	5.04	9.5	12.6
		24	1.04	3.12	4.16	7.8	10.4

However, if the more typical lateral wash-water gutter is considered, in which the water is coming in both sides in equal increments, for a 40-ft channel, 2 ft wide, between 7.8% and 10.4% of the wash water has not entered the gutter at the control. The two plants illustrated are among the larger plants in the United States. Many plants have lateral wash-water gutters 10 ft or less in length. If $l = 10$ ft and $b = 12$ in., with $q = 0.3$ cu ft per sec per foot of gutter, the quantity of water entering after the control is between 19.5 and 26.0 per cent. The greater the length for a given increment of flow, and the larger the value of b, the more nearly correct is the author's assumption. Naturally, the greater the rate of washing, the greater will be the value of d_c. Although the author's assumption is fundamentally unsound, it provides a means for calculating an artificial but apparently reliable starting point for the water-surface curve.

With the foregoing facts and a simplification of Equation (29), design computations may be simplified to a less general, but easier, method than that proposed by the author.

If

$$2\,S\,x_c\,\bar{d} = \frac{f\,x_c\,d_c^3}{12\,\bar{R}\,\bar{d}} \qquad (44)$$

Equation (29) becomes

$$H_0 = \sqrt{3}\,d_c \qquad (45)$$

and there appears to be no reason why this condition cannot be obtained for the usual channel, since physically it implies giving the channel slope enough to compensate for the assumed friction. From Equation (44) there results a unique and simple relation between S and f which permits the designer to observe the effect of the assumed f upon the slope of the channel. This relation is

$$\frac{S}{f} = \frac{d_c^3}{24}\,\frac{1}{\bar{R}\,\bar{d}^2} \qquad (46)$$

and may be placed in more practical form by the following relations

$$\bar{d} = \frac{H_0 + d_c}{2} \qquad (47a)$$

and

$$\bar{R} = \frac{\left(\dfrac{H_0 + d_c}{2}\right) b}{H_0 + d_c + b} \qquad (47b)$$

which are approximate, but permissible when the uncertainty in the selection of f is considered. Insertion of these values in Equation (46) results in

$$\frac{S}{f} = \frac{d_c^3}{3}\left[\frac{H_0 + d_c + b}{(H_0 + d_c)^3\,b}\right] \qquad (48)$$

which, with Equation (45), and the critical-depth formula, Equation (28), allows quick calculation of the principal dimensions of the spillway channel.

Equations (45), (48), and (28) may be used by the designer to give values for the size of lateral wash-water troughs which, while approximate, are as accurate as the value of "f" which must be assumed.

In the design of a system of wash-water troughs it is first necessary to assume a layout (as dictated by practice) and then investigate that particular layout. For any spacing of gutters there are an infinite number of breadths of gutter which can be used, but experience has shown that the wash-water gutters should not occupy more than one-third of the surface area. The applicability of Equations (45), (48), and (28) to design is given in the following illustrative problem.

The wash-water troughs are 20 ft long, spaced 6 ft on centers, and designed to carry a wash-water rate of 36 in. vertical rise per minute. In the illustrative computations a breadth of 12 in. was used, but Table 4 gives results for a breadth of 24 in. also. The inflow, q, per lineal foot of trough is given by $q = \frac{36}{60 \times 12} \times 6 = 0.3$ cu ft per sec per ft; the total flow Q is equal to $0.3 \times 20 = 6.0$ cu ft per sec; from Equation (28) $d_c = \sqrt[3]{\frac{(6.0)^2}{32.2 \times 1^2}} = 1.04$ ft; and, from Equation (45) $H_0 = \sqrt{3} \times 1.04 = 1.80$ ft. Substituting in Equation (48), $\frac{S}{f} = 0.063$. It is now necessary to assume a value of f. Many more experimental data are necessary before this value can be predicted accurately; but values of f of 0.03 and 0.10, from the author's data, will require respective slopes of 0.0019 and 0.0063.

TABLE 4.—COMPARISON OF APPROXIMATE DESIGN DATA FOR TWO, TWENTY-FOOT, WASH-WATER TROUGHS

Width of trough, b, in feet	Flow		Depth, d_c, in feet	Head, H_0, in feet	Ratio, $\frac{S}{f}$	Slope, S	
	q, in cubic feet per second per foot	Q, in cubic feet per second				For a friction factor, $f = 0.030$	For a friction factor, $f = 0.10$
1.0	0.30	6.0	1.04	1.80	0.063	0.0019	0.0063
2.0	0.30	6.0	0.653	1.13	0.0312	0.00094	0.00312

The foregoing computations are summarized in Table 4, which includes for comparison the results obtained from the same filter when a value of $b = 24$ in. is assumed. It is interesting to note that the value of S for a given value of b and f varies quite widely. A variation of f from 0.030 to 0.10 requires an increase of slope from 0.0019 to 0.0063 for a 12-in. width and from 0.00094 to 0.00312 for a 24-in. width. As would be expected from Equation (48), for all other items constant S varies directly with f; that is, the slope required for $f = 0.10$ for either a 12-in. or a 24-in. width is 3.33 times the slope required for $f = 0.03$. It is granted that these simplifications of the author's formula give only approximate results; but they are as accurate as the values of f. There is need for further research to determine the value of f for short channels, particularly on short wash-water lateral gutters and trickling filter collection troughs.

Presumably the experimental channel at Massachusetts Institute of Technology did not have free outfall according to the surface curve of Fig. 6.

F. KNAPP,[10] ESQ. (by letter).—This paper, treating a special chapter of applied hydraulics, should command the interest of all engineers interested in problems involving the flow of water in open channels. The author's treatment of the question is so complete that scarcely any improvement is possible. The same problem is being encountered in the design of tail-races for hydro-electric plants with laterals connecting the main channel with the turbine pits.

The author mentions a formula based upon the assumption that the draw-down of the water surface is equal to the velocity head. Rearranging Equation (17) and using the Manning flow formula instead of the Weisbach equation, the following is obtained:

$$dy = \frac{V^2}{g}\left(\frac{g}{K^2\,R^{\frac{4}{3}}}\,dx + \frac{dQ}{Q} + \frac{dV}{V}\right)\ldots\ldots\ldots\ldots\ldots(49)$$

in which $dQ = q\,dx$. The roughness factor K of Manning's formula is approximately equal to the reciprocal of Kutter's "n"; and R is the hydraulic radius of the spillway channel.

Equation (49) indicates the causes for the draw-down of the water level—namely, friction, increase of discharge and change of velocity. A comparison of this formula with the more general expression derived by H. Favre [11] shows that the derivation neglects the component of the velocity of the lateral discharge parallel to the axis of the flume, as well as the non-uniform velocity distribution of the flow in the channel. However, only in exceptional cases need these factors be taken into account and for this reason Equation (17) is perfectly general.

Equation (29) is only valid for the case with critical depth at the downstream end of the spillway channel. Neglecting, for the moment, the slope S of the channel and the friction, Equation (29) may be written:

$$H_0 = \sqrt{3\,d_c^2} = d_c\,\sqrt{3}\ldots\ldots\ldots\ldots\ldots\ldots(50a)$$

Note the comparison with the rearranged Equation (23):

$$H_0 = d\sqrt{2\left(\frac{d_c}{d}\right)^3 + 1}\ldots\ldots\ldots\ldots\ldots\ldots(50b)$$

Equation (50b) is valid in all cases, including the freely discharging flume.

The author calls attention to the difference between lateral spillway channels and side weirs. As shown by Mr. Favre,[12] Equation (17) is also valid for the case of a side weir provided the term $\frac{dQ}{Q}$ is disregarded. Therefore:

$$dy = \frac{V^2}{g}\left(\frac{g}{K^2\,R^{\frac{4}{3}}}\,dx + \frac{dV}{V}\right)\ldots\ldots\ldots\ldots\ldots(51)$$

This equation is exactly equal to the well-known expression for the computation of back-water curves. However, there is a fundamental difference between the two formulas. The condition of continuity in the case of the back-water curve is:

[11] "Contribution a l'Étude des Eaux Courants," by H. Favre, Editor Rascher & Cie., Zurich, Leipzig and Stuttgart, 1933, Equation (14), p. 17.

[12] *Loc. cit.*, p. 60.

$$V_2 A_2 - V_1 A_1 = 0 \qquad (52a)$$

and in the case of the side weir:

$$V_2 A_2 - V_1 A_1 = \Delta Q \qquad (52b)$$

in which A is the cross-sectional area of the canal and ΔQ is the discharge over the side weir.

The model tests conducted by Mr. Favre[13] at the "Laboratoire des Recherches Hydrauliques Annexé à l'École Polytechnique Fédéral de Zurich" have shown that in the case of tail-race channels for hydro-electric power stations, it becomes necessary to apply Equation (17) neglecting the friction term. This procedure counterbalances, partly, the error due to the velocity component of the lateral flow, which is always present.

The smooth surfaces of the experimental profiles, given by the author, represent a most surprising fact. Observations made on lateral spillway channels for dams always indicate a very wavy profile, the theoretical surface of the water passing through the centers of these waves.

The author is to be commended for his most interesting, useful, and timely paper.

Carl Rohwer,[14] Assoc. M. Am. Soc. C. E. (by letter).—The applicability of the momentum principle to the general solution of the problems arising in the design of side channel spillways has been demonstrated by Mr. Hinds[2] and Mr. Favre.[3] The analysis presented in this paper shows the application of the principle to the special case of the design of wash-water gutters, with a consequent simplification in the procedure.

The experimental data presented by these investigators show that the calculated water-surface profiles are in reasonably close agreement with the observed profiles. This fact seems remarkable in view of the assumptions that must be made in order to simplify the theoretical analysis. For example, to compute the momentum at any section in the channel, it is necessary to know the average velocity of the water at the section. It is assumed to be equal to the discharge at the section divided by the area. Actually, the velocity in any section may vary through wide limits; some of the velocities may even be negative. It is evident, therefore, that the average velocity is greater than the mean computed in this manner. Since the average depth of the water in the channel is used in computing the velocity, entrained air which increases the indicated depth will tend to increase the difference between the average and the mean velocity still further. The total difference will depend on the depth of water flowing into the channel and on the turbulence produced.

The photographs presented by Messrs. Hinds and Favre show that the water flowing over the spillway crest creates a violent disturbance in the water, and may produce a definite transverse roll. The writer has observed spillway models in operation, and although the depth of water flowing over the weir into the channel did not exceed 6 in. in these model studies, the agitation of the water was pronounced. From the foregoing discussion, it is apparent that there are important differences between the assumed and observed conditions. There may be compensating factors, however, which tend to minimize the effect of the errors in these assumptions.

[14] Irrig. Engr., Div. of Irrig., SCS, U. S. Dept. of Agriculture, Colorado Experiment Station, Fort Collins, Colo.

In evaluating the friction factor "*f*" (see heading "Experimental Evaluation of Friction Factor") by substituting in Equation (23) the channel depths observed during tests made on several spillways, the author found values ranging from 0.033 to 0.11; and, in one case the value of "*f*" was negative. The wide range in the friction factors leads the writer to believe that part of the variation is due to the fact that the formula does not agree precisely with the experimental data and that, in effect, the friction factor becomes a coefficient that takes care of the difference between the observed and computed data as well as the friction in the channel.

The use of a friction factor derived in this manner in computing the depths for the profiles (Figs. 4, 5, and 6) by substituting in the formulas would tend to make the computed results agree more closely with the observed results than the accuracy of the formulas warrants. In designing a channel for a wash-water gutter, it would be necessary to assume a value of "*f*"; and consequently the computed profiles might not agree so closely with those observed in the actual structure. It would have been helpful if the author had included in this paper a table of values of "*f*" for use by any one having to design a spillway of this kind.

HAROLD ALLEN THOMAS, JR.,[15] ESQ. (by letter).—Professor Camp has successfully applied the momentum principle in the analysis of flow in lateral spillway channels of constant width and slope. His ingenious integration of the differential equation provides a general method of calculating the profile of the water surface in a wash-water gutter or gulley. The profiles obtained by his method coincide closely with the measured water surfaces over a large part of the length of the channel. It should be emphasized, however, that the hydraulic theory underlying his analysis does not apply to flow with sharply curving stream-lines and, as a consequence, the differential equation (Equation (17) or (18)) fails in the vicinity of the outfall, as he has shown. In the absence of actual measurements in this region the full success of his analysis is predicated upon the adequacy of empirical rules giving the position of such points as the critical depth in relation to the outfall.

The author's statement (see heading "Critical Depth") that "a close approximation to actual conditions will be obtained if a hydrostatic control section is assumed to exist at a distance up stream from the end equal to three or four times the critical depth" appears to be somewhat arbitrary. In working out a number of surface curves it has been found that it may make a considerable difference whether the "three" or the "four" in the above quotation is used. Moreover, there is no assurance that the effective control section will remain within these limits under all conditions of flow. The writer has experimental evidence that clearly indicates a somewhat wider variation in the position of the effective control section depending upon slope and discharge in the channel than that suggested by the author. Thus it would appear that, to attain the full degree of precision offered by the author's method, it is necessary to have more exact knowledge of the position of the effective control section. Indeed, it has been found that the uncertainty of the location of the effective control section frequently obscures the refinement of introducing the friction term into the formulas. Consequently, in the absence of more complete experimental information regarding the curve of the water surface near the outfall, the inclusion of the friction term, in many cases, is wasted effort.

---

[15] Instr., San. Eng., Graduate School of Engineering, Harvard Univ., Cambridge, Mass.

However, in the design of wash-water troughs there may be some question as to the necessity of a complete, meticulous analysis of the flow. From the standpoint of the designer, it usually suffices to know what depth of water to expect in the upper end of the channel under a particular set of conditions. It is seldom necessary in conventional design to compute the entire profile of the water surface. During the past two decades a great many wash-water gutters have been designed in accordance with equations giving the depth of water at the upper end of the channel. In spite of being only semi-rational and containing arbitrary coefficients, these formulas do possess the virtue of simplicity. It seems possible, given the differential equation developed by the author, that a simple formula might be derived for the depth of water at the upper end of the channel (H_0) in terms of the discharge, length, width, and slope, that would eliminate the necessity for successive approximations, as well as the element of trial and error, and yet provide sufficiently precise information for purposes of design.

The foregoing opinion was expressed to the writer by G. M. Fair, M. Am. Soc. C. E., in the hope that an investigation might reveal a suitable basis of simplification. Of course, such simplification, to be of any real value, would have to yield formulas capable of giving more reliable results than semi-empirical formulas used in the past. As a method of approach to the problem, Professor Fair suggested that the integrals in Equation (20) might be evaluated by replacing d by a second degree function of x. In checking various formulas developed according to this scheme with observed water surfaces in wash-water gutters, it was found that the friction term, involving f, made practically no contribution to the precision attained. Since the inclusion of friction forces complicated the formulas considerably, it was believed that a reasonable compromise between precision and simplicity resulted from the omission of the friction term entirely. Therefore, in the equations that follow, friction has been neglected.

The success of the analysis according to Professor Fair's scheme was found to depend upon the selection of the second degree function of x to be substituted for d in the remaining integral of Equation (20). The function finally chosen was a parabola that adheres rather closely to observed water surfaces. The arbitrary constants of the function were so chosen as to cause the parabola to coincide with the actual surface at $x = 0$ and $x = x_c$ and, further, to possess a slope of S when $x = 0$ as is required by Equation (18). This function of d in terms of x is as follows:

$$d = H_0 + S\,x + \frac{(d_c - H_0 - S\,x_c)\,x^2}{x_c^2} \qquad \text{.............(53)}$$

When this value is placed in Equation (20) and if $f = 0$, the following equation may be written:

$$\frac{x^2}{d} + \frac{g\,b^2\,d^2}{2\,q^2} = \frac{S\,g\,b^2}{q^2}\int\left[H_0 + S\,x + \frac{(d_c - H_0 - S\,x_c)}{x_c^2}\,x^2\right]dx + c \ldots \tag{54}$$

Since $\frac{g\,b^2}{q^2} = \frac{x_c^2}{d_c^3}$, and since $d = H_0$ when $x = 0$, the integrated equation may be written in the following form:

$$\frac{x^2}{d} + \frac{x_c^2}{2\,d_c^3}\,(d^2 - H_0^2) = \frac{S\,x_c^2}{d_c^3}\left[H_0\,x + \frac{S\,x^2}{2} + \frac{(d_c - H_0 - S\,x_c)}{3\,x_c^2}\,x^3\right] \ldots \tag{55}$$

Substituting $x = x_c$ and $d = d_c$ and solving for H_0, the final formula is

$$H_0 = \sqrt{2\,d_c^2 + \left(d_c - \frac{S\,x_c}{3}\right)^2} - \frac{2}{3}\,S\,x_c \ldots\ldots\ldots\ldots \tag{56a}$$

In comparing values of H_0 given by Equation (56*a*) with those obtained by measurement of the water surface over a wide variety of slopes and discharges, a rather close agreement was observed. In addition, it was found that the degree of precision attainable by this formula was not appreciably affected by taking x_c equal to the entire length of the channel (L), and d_c as calculated from the entire discharge by the formula $d_c = \sqrt[3]{\frac{Q^2}{g\,b^2}}$. Accordingly, Equation (56*a*) becomes

$$H_0 = \sqrt{2\,d_c^2 + \left(d_c - \frac{S\,L}{3}\right)^2} - \frac{2}{3}\,S\,L \ldots\ldots\ldots\ldots \tag{56b}$$

For $S = 0$, Equation (56*b*) reduces to

$$H_0 = 1.73\,d_c \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \tag{57}$$

A number of rapid sand filter plants are designed or operated in such a manner that the wash-water does not discharge freely from the gutters to the central gulley. In this case the height of the water surface in the lower end of the channel exceeds that occurring with free discharge, and is determined by hydraulic conditions down stream. Therefore, if the hydraulic control lies beyond the gutter, the use of equations based on free discharge may involve considerable error. It is of interest to the designer to know what depth of water to expect in the upper end of the wash-water gutter for various depths in excess of the critical depth at the lower end of the channel. This depth of water (H_0), at the upper end of the channel, is given by the following formula, which was derived in the same manner as Equation (56*a*), for the condition $x = L$, $d = d_L$ (where d_L is the measured or expected depth of water at the lower end of the channel).

$$H_0 = \sqrt{\frac{2\,d_c^3}{d_L} + \left(d_L - \frac{S\,L}{3}\right)^2} - \frac{2}{3}\,S\,L \ldots\ldots\ldots\ldots \tag{58}$$

and for $S = 0$ this reduces to:

$$H_0 = \sqrt{\frac{2\,d_c^3 + d_L^3}{d_L}} \ldots\ldots\ldots\ldots\ldots\ldots \tag{59}$$

It is to be noted that Equation (56*b*) may be obtained from Equation (58) by making $d_L = d_c$.

For the convenience of the designer the relationship given by Equation (58) (including the special cases covered by Equations (56*b*), (57), and (59)) could be easily expressed in the form of a diagram.

The order of agreement obtained using Equations (56*b*) and (59) with the method of the author for the various sets of experimental measurements included in his investigation is indicated in Table 5. The comparison is based on the quantity $H_0 + L\,S$, since this represents the actual over-all head in the channels.

The average error in Table 5 is 1.5% and it may be noticed that the largest discrepancy, occurring in the Division Avenue Plant, is only 3.8 per cent. This should serve to demonstrate that the divergence between the two methods is quite small; in fact, it may actually fall within the limits of experimental error inherent in the measurement of water depths and discharge.

In order to investigate further the precision offered by Equations (56*b*), (57), (58), and (59) under a wide range of channel slopes and discharges, a small lateral spillway channel was constructed and tested in the Gordon McKay Engineering Laboratory of Harvard University, at Cambridge, Mass. This channel, made of cypress, was 5 ft 11 in. long and 4 in. wide, with level top edges and bottom of adjustable slope. Experience has demonstrated that the results obtained from model channels of this size and type may be translated to pertain to structures of larger dimensions by application of the ordinary Froude law of hydraulic similitude. Investigations with this channel proved to be satisfactory in every respect.

A summary of the degree of accordance between Equations (56*b*) and (57) and experimental information acquired from measurement of the water surface at the upper end of the channel under various conditions of slope and flow with free discharge at the outfall is presented in Table 6. In Table 6, as before, the comparison is based upon the quantity $H_0 + L\,S$ for convenience in comparing tests of different slope.

In Table 6 the average absolute error is only 2.2%, and the largest error is 5.5%, occurring with a slope of 0.0313 and a relatively small discharge. Although these errors are small, it should be pointed out that, with increasing slopes, the velocities in the channel become larger and the friction term becomes of increasing importance. Hence, it is not expected that Equations (56*a*), (57), (58), and (59), in which this term is neglected, will apply indefinitely. Using these equations with slopes greater than 0.055, errors in excess of 15% have been found. Such slopes, however, involve an uneconomical channel design; it will be shown that Equations (56*a*), (57), (58), and (59) are valid for the range of slopes occurring in economically designed channels.

In Table 7 is presented a summary of experiments in which the hydraulic control section did not occur in the channel. In these tests the depth of the water in the lower end of the gutter exceeded the critical depth. To show the extent to which the water was backed up in excess of the critical depth, the quantities d_c and d_L have been included in Table 7. The depths $H_0 + L\,S$ measured at the upper end of the channel are compared with corresponding depths in this region calculated with Equations (58) and (59).

The average absolute error in Table 7 is 2.8%, and the maximum error does not exceed 5 per cent. This is in agreement with the order of precision attained in the other experiments. Therefore it can be concluded that Equations (56*a*), (56*b*), (57), (58), and (59) give sufficiently precise information for practical purposes. Indeed, under many conditions, the error involved in using these equations is of a considerably smaller magnitude than the errors that result in practice from incorrectly estimated discharges and improperly leveled weir crests.

Economics of Wash-water Gutter Design.—An interesting application of Equation (56*b*) is the determination of the slope of the most economical wash-water gutter, assuming that Q, b, and L are specified by the rate of back-wash and filter-bed dimensions. The cost of a wash-water gutter may be taken as the cost of the sides and bottom and, in addition, certain fixed costs that do not depend upon the dimensions of the channel. This may be stated mathematically as follows:

$$C = 2\,K_s\,L\left[\frac{H_0 + (H_0 + L\,S)}{2}\right] + K_b\,b\,L + K_f \ldots\ldots\ldots (60)$$

in which C = cost of channel; K_s = cost of sides per unit area; K_b = cost of bottom per unit area; and K_f = fixed costs (assumed to be independent of dimensions of the channel). Substituting the value of H_0 from Equation (56*b*), Equation (60) becomes

$$C = K_s\,L\left[2\sqrt{2\,d_c^2 + \left(d_c - \frac{S\,L}{3}\right)^2} - \frac{S\,L}{3}\right] + K_b\,b\,L + K_f \ldots (61)$$

Since Q, b (hence d_c), L, K_s, K_b, and K_f are constants, the cost of the channel depends only upon the value of S. Differentiating Equation (61) with respect to S and setting the derivative equal to zero:

$$2\left(d_c - \frac{S'\,L}{3}\right) = -\sqrt{2\,d_c^2 + \left(d_c - \frac{S'\,L}{3}\right)^2} \ldots\ldots\ldots (62)$$

Solving for S', the slope corresponding to minimum cost of channel,

$$S' = 0.55\,\frac{d_c}{L} = \frac{0.55}{L}\sqrt[3]{\frac{Q^2}{g\,b^2}} \ldots\ldots\ldots (63)$$

From Equation (63) it may be seen that the optimum slope increases with discharge and decreases with the length and width of the channel. For average values of Q, L, and b used in the United States the most economical slope, according to Equation (63), usually falls between 0.0125 and 0.0175.

Conclusions.—It has been shown that the author's elaborate treatment of flow in lateral spillway channels, for practical purposes, may be simplified into elementary formulas or diagrams that show a remarkable agreement with experimental measurements. These formulas lend themselves to an analysis of the economics of wash-water gutter design in which a rule is developed for the determination of the optimum slope of the channel.

THOMAS R. CAMP,[16] M. AM. SOC. C. E. (by letter).—The discussion of this paper has been gratifying particularly because of its quality. Professor Howland presents a helpful rule for approximating the drop in water surface quickly. Professor Carpenter and Messrs. Vennard and Whitley suggest a unique procedure for simplifying design, whereby both the slope and friction terms in the equation are eliminated by equating them. Mr. Knapp rearranges the differential equation in a manner to indicate each factor which contributes to the draw-down of the water surface, and he also points out the applicability of the differential equation to side weirs. Mr. Rohwer rightfully questions the utility of the Hinds-Favre equation for large spillways where violent rollers and entrained air are of paramount importance. Mr. Thomas presents a useful development of the economics of wash-water gutter design. The writer wishes to express his appreciation for these helpful contributions.

Professor Howland's Equation (41) for computing the drop in water surface between two sections a distance Δx apart is of general applicability, regardless of the shape of the flume. To this extent it is more useful than the writer's integrated form (Equation (23)), which applies only to rectangular channels of constant width and slope. The use of Equation (41) for the more simple channels, however, is more laborious than the writer's method. Even for the evaluation of f from measurements of the water surface, Equation (23) is probably more direct and more simple than Equation (41). It possesses the added advantage of producing, immediately, the average value of f for the entire stretch of channel being investigated.

In a first approximation of the value of H_0 in channels where the depth d at a section at or near the lower end is known, Professor Howland neglects the second and third terms of Equation (41). The total drop is thus approximately equal to twice the velocity head at the section where d is known. This approximation is not a safe procedure, although in the examples cited it does produce results that are not widely in error. The last two terms in Equation (41) do tend to compensate for one another, but the assumption that they are equal may be too greatly in error for reliability. The second term depends upon the slope of the bottom, is negative for a level bottom, approaches zero as the bottom slope becomes nearly parallel with the water surface, and may become positive for bottoms with steep slopes. For a level bottom and a hydrostatic control section at the lower end, the sum of the first two terms is $1.46 \frac{V^2}{2g}$, as may be seen from Equation (45). The drop in the water surface due to the friction term bears little relation to the second term of Equation (41). In the writer's examples the friction drop is from 6,5% to 16% of the total drop.

Professor Howland's proposal to use vanes in order to utilize a part of the momentum of the inflowing water and thus increase the capacity of the channel is worthy of investigation for dam spillways. Some knowledge of the value of the friction losses in such large channels is necessary, however, before one can be sure that the vanes are worth their cost. Undoubtedly, the friction losses are large, but it is doubtful if they are so large as to permit of an increase in capacity of 50% by their reduction.

---

[16] Associate Prof. of San. Eng., Mass. Inst. Tech., Cambridge, Mass.

Messrs. Carpenter, Vennard, and Whitley note that the values of f as found by the writer for lateral spillway channels are greater than the usual values of 0.02 or 0.025 for uniform flow in pipes. The increase in the value of f is undoubtedly due to the greater turbulence resulting from the impact of the incoming water. The table of values of f as presented by the writer is indeed meager, but all data which were available were used. It is hoped that other data will become available in the future for the evaluation of f. It will be very helpful if values of f can be obtained from some full-scale dam spillways where air entrainment and rollers are pronounced. Until some such efforts are made, the validity of the Hinds equation for the design of such structures is in doubt. It will be noted from the data presented in Table 1 that the value of f increases as the increment of inflow increases. One may surmise that with dam spillway channels, where the inflow increment is much greater, the value of f may be very much larger than the values in Table 1.

The writer's statement (see heading "Critical Depth") that "For the design of freely discharging flumes, a close approximation to actual conditions will be obtained if a hydrostatic control section is assumed to exist at a distance up stream from the end equal to three or four times the critical depth" has been criticized by Messrs. Carpenter, Vennard, and Whitley and again by Mr. Thomas. The proper distance to take, of course, will be influenced by the shape of the outlet end of the flume, the discharge, the amount of submergence or degree of aeration of the discharging stream, and probably other factors. If a hydrostatic control section is assumed to exist at the end, the design will be on the safe side, but it may be uneconomical. The arbitrary figure of "three or four" times the critical depth should be tempered by the judgment of the designer. In the case of the Detroit experiments (Fig. 4), the distance was 3.8 and 4.3 times the critical depth for Run No. 1 and Run No. 2, respectively. In the case of the Baldwin Filtration Plant experiment (Fig. 5(b)), the distance was 1.25 times the critical depth. For the Division Avenue Plant experiment (Fig. 5(a)) the critical depth was substantially at the end of the channel; but this channel can scarcely be said to be discharging freely. The experimental channel at the Massachusetts Institute of Technology was provided with means below the outlet end for controlling the depth of flow, and for the run presented in Table 1 and Fig. 6 the outlet end was submerged.

In applying the arbitrary rule of three or four times the critical depth, the value of d_c should not be computed from the total channel discharge, but rather from the inflow up stream from the assumed position of the hydrostatic control section. As has been noted by Messrs. Carpenter, Vennard, and Whitley, a portion of the wash water will enter the channel below the control. Since this water is discharged at lower stage, it does not influence the shape of the water-surface curve above the control.

If a hydrostatic control is assumed to exist at the outlet end, the computed value of H_0 will be too great. If a hydrostatic control is assumed at the proper distance up stream but the total discharge is used for computing d_c and H_0, the value of H_0 will be too great again. Moreover, since q has thus been made too great, the water-surface curve will be distorted. If the hydrostatic control is assumed at the proper distance up stream and computations are based upon the inflow above this section, a correct value of H_0 will result, and the computed shape of the water surface curve will coincide with the actual almost down to the assumed position of the control. It will be noted from Figs. 4 and 5, however, that the actual depth at the assumed position of the control is likely to be greater than d_c. This is due to the prevalence of vertical accelerations in this region which result in pressures less than hydrostatic.

The approximate values of $\bar{d}$ and $\bar{R}$ as given in Equations (47*a*) and (47*b*) are based upon a straight water-surface profile. Since the profile is more nearly parabolic in shape, better approximations for $\bar{d}$ and $\bar{R}$ may be obtained from the following equations:

$$\bar{d} = \frac{2\,H_0 + d_c}{3} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (64a)$$

and

$$\bar{R} = \frac{\left(\dfrac{2\,H_0 + d_c}{3}\right) b}{2\left(\dfrac{2\,H_0 + d_c}{3}\right) + b} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (64b)$$

If design data are computed for the two 20-ft wash-water troughs of Table 4 on the basis of these relations and Equation (46), the ratio $\frac{S}{f}$ becomes 0.052 for the trough 1 ft wide and 0.025 for the 2-ft trough.

The scheme proposed by Messrs. Carpenter, Vennard, and Whitley for simplifying the design of wash-water gutters by equating the slope term to the friction term, as shown by Equation (44), raises the question of the desirability of fixing the slope for the sole purpose of simplifying computations. If this is the aim, a simpler procedure is to make the bottom level. With a level bottom, H_0 may be approximated very quickly by computing the drop in the water surface from Equation (45) and increasing it by about 10% to allow for friction. There are advantages in a level bottom from both a construction and an operating viewpoint. However, neither a level bottom nor a bottom having a slope as obtained by Equation (44) is consistent with best economy of materials. Applying Mr. Thomas' Equation (63), one obtains an economical slope of 0.0286 for the 1-ft trough of Table 4 and 0.018 for the 2-ft trough. These slopes are much greater than those required by Equation (44).

Mr. Knapp points out that Equation (17) neglects the component of the velocity of the lateral inflow parallel to the axis of the flume, which component was considered in the Favre equation. In the horizontal plane no such component exists for the small channels dealt with by sanitary engineers. For such channels the inflow usually approaches at right angles to the axis of the flume. Such may not be the case, however, for dam spillways and for tail-race channels of hydro-electric power stations. Both Mr. Knapp and Mr. Rohwer suggest that an additional error is introduced by the use of the $\frac{Q}{A}$-velocity instead of the actual velocity, which varies widely over the cross-section. This appears to be the case since the actual momentum in an axial direction is somewhat greater than that computed by means of the mean velocity at the cross-section. This error is thrown into the value of f and tends to make it larger than it would be if the correction were made. Evidently, the error is small since the values of f obtained are not unreasonably large.

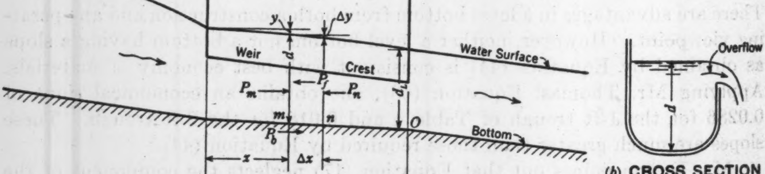
Both Mr. Knapp and Mr. Rohwer appear surprised at the apparent smoothness of the profiles of the water surface as shown in the illustrations of the paper. Although it is true that the water surface in these small channels was much smoother and had much less entrained air than is the case with dam spillway channels, the surface is always rough and transverse rollers are always present. Each point plotted on the curves to represent a measured point on the surface of the water is the average of at least two readings.

Mr. Thomas' suggested simplification of the writer's equations by the introduction of an empirical function for the depth seems quite as complicated as the writer's more rational development. The use of the empirical function, moreover, obscures the friction term in the equations. Since the friction term varies with the increment of inflow, large errors may result by the indiscriminate use of the empirical function.

It may be of interest to demonstrate how the differential equation (Equation (17)) may be applied to the analysis of the flow conditions for side weirs. The case is illustrated diagrammatically in Fig. 8. The development of Equation (17) follows in the same manner as previously presented except that for this case the lateral flow is outward and the increment (a decrement in this case) is not constant over the length of the side weir. Equation (17) becomes

$$\frac{dy}{dx} - \frac{f\,V^2}{8\,g\,R} = \frac{1}{g}\left(V\,\frac{dV}{dx} + \frac{V^2\,dQ}{Q\,dx}\right)\ldots\ldots\ldots\ldots\ldots(65)$$

in which $\frac{dQ}{dx} = q$. It is impractical because of the increased number of variables and the difficulty of integration to obtain an integral in terms of the depth for this equation. A "trial-and-error" solution may be obtained, however, in terms of the water-surface profile, in a manner similar to that suggested by Professor Howland for the lateral spillway channel.



(a) LONGITUDINAL SECTION SHOWING SIDE WEIR

(b) CROSS SECTION FACING UPSTREAM

FIG. 8

Equation (65) may be written

$$dy = \frac{f}{4\,R}\,\frac{V^2}{2\,g}\,dx + \frac{V}{g}\,dV + \frac{1}{g}\,\frac{Q}{A^2}\,dQ \ldots\ldots\ldots\ldots\ldots (66)$$

This equation may be integrated approximately over the short distance Δx as follows:

$$\Delta y = \frac{f}{4\,R_{av}}\left(\frac{V^2}{2\,g}\right)_{av}\Delta x + \frac{V_n^2 - V_m^2}{2\,g} + \frac{Q_n^2 - Q_m^2}{2\,g\,(A^2)_{av}} \ldots\ldots\ldots (67a)$$

or

$$\Delta y = \frac{f}{4\,R_{av}}\left(\frac{V^2}{2\,g}\right)_{av}\Delta x + \frac{V_n^2 - V_m^2}{2\,g} + \frac{\Delta Q(Q_n + Q_m)}{2\,g\,(A^2)_{av}} \ldots\ldots (67b)$$

The design may be started at the down-stream end (point o) where d_L, A, and Q are fixed to suit the requirements of the problem. For an assumed value of Δx and a corresponding value of ΔQ to suit the conditions of the problem, a trial position of the weir crest may be set for the down-stream end, and an estimate made of the value of the first Δy. After suitable adjustments are made, the process may be continued for succeeding values of Δx up stream until a length of weir is obtained which will deliver the required overflow.

THEORY OF LIMIT DESIGN

By J. A. Van den Broek,[1] M. Am. Soc. C. E.

With Discussion by Messrs. John H. Meursinge, I. K. Silverman, Edward Godfrey, Basil Sourochnikoff, E. Mirabelli, C. M. Goodrich, George Winter, Francis E. Simpson, Joseph A. Wise, Alfred Freudenthal, Hans H. Bleich, Alfred S. Niles, A. Floris, L. H. Nishkian, F. G. Eric Peterson, E. S. Fabian, A. A. Eremin, L. H. Donnell, and J. A. Van den Broek.

Synopsis

This paper shows that the capacity load which a redundant structure can carry is not limited to the load that stresses one member to the elastic limit. In fact, the capacity load of a structure is reached only after as many members of a structure, corresponding in number to the structure's redundants, have all reached their elastic or buckling limit strength. As a load is gradually applied to a structure, its redundant members, in general, are successively stressed, one after another, until they reach their elastic or buckling limit strength. The remaining members may be designated as the primary system which still behaves elastically, and which can carry a still greater load, safely, until one of its members is likewise stressed to the elastic or buckling limit strength. This final load condition is defined as the "capacity load" upon which the design of the structure is based. Thus, if a structure is to have a factor of safety of two, the specified loading is doubled and the designer would find the "limit design" that would permit the redundant members in the structure to reach their elastic limit, or buckling strength. If so loaded some slight permanent set and some residual stresses might result, but the deformations of the structure would still be of the order of magnitude of elastic deformations. The structure could carry half the limit load safely, without any member being stressed to the elastic limit.

Introduction

Traditionally all theory pertaining to the strength of materials and to structural design is based on two major assumptions: (1) That the material is elastic; and (2) that the principle of superposition applies. To be sure, excep-

---

Note.—Published in February, 1939, *Proceedings*.

[1] Prof. of Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

tional problems, to which the principle of superposition does not apply, are treated by successive approximations, but even then the theory of elasticity is followed. In the common problem of designing rivet connections another assumption is introduced; namely, that the stresses are distributed equally over all rivets. Very little is said about that assumption other than that it represents established engineering practice. Recently, considerable attention has been paid to various theories of failure. However, the emphasis is placed upon the theory of the failure of materials rather than upon the theory of the failure of structures. The emphasis always has been, and continues to be, directed toward the analysis of stresses.

The man engaged in studies by photo-elasticity sees nothing but strains and talks about nothing but stress. If the theory of columns reveals anything, it is the critical, limit, load of the column, but designers are so much the creatures of habit that they must divide this load by area in order to get back again to talking about stresses. When a structural engineer adopts what is known as "good structural steel," he writes his specifications mostly with reference to stresses, and he expresses his theory in terms of stresses. Practically, however, no bridge or steel frame ever breaks; failure or collapse is the result of excessive deformation. To be sure, in a heap of wreckage it may be possible to find a ruptured steel bar; but there is not one chance in a million that this ruptured bar was the cause of the failure. Structural engineers wax enthusiastic about compound stresses, maximum stresses, working stresses, and critical stresses; in fact, they talk so much about stresses that it would seem that, if they only knew enough about them, they would not need to inquire into anything else. In this connection it is of interest to refer to an experiment[2] conducted in 1912 in which bars were broken as the result of excessive elongations. In every respect, the break resembled a tensile fracture with no stresses acting in the plane of fracture at the time of rupture. If any stresses were acting on this plane they were compression stresses as a result of friction in the packing, created as the bar was squeezed through (see Fig. 1).

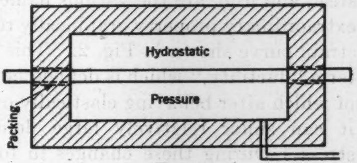

FIG. 1

This emphasis on stresses may have been acceptable in the past when civil engineering structures were statically determinate. In such structures each bar, each member, and each cross-section has a definite task to perform. There being no other member or restraint present to relieve conditions, the passing of the elastic limit stress means that excessive deformations of the order of magnitude of ductile deformations (say, from 5% to 10% of the length of the member) will take place without a corresponding increase in the carrying capacity of the structure; and that therefore the usefulness of the structure is brought to an end. Even in that case the excessive deformation is the primary, and the accompanying stress the secondary, consideration. So long as there is a direct relation between the two no practical harm results. However, as long as the engineer continues to talk about stresses when he means deformations, he violates sound engineering philosophy. In the consideration of compression members the logic is essentially the same as that applied to tension members. When a compression member is loaded to its capacity buckling load, although the deformations may continue for a time to be within the elastic range, excessive deformations take place, marking the limit capacity of the structure of which the column is a part.

---

[2] "Breaking Tests under Hydrostatic Pressure and Conditions of Rupture," by P. W. Bridgman, *Philosophical Magazine*, July, 1912.

In the study of statically indeterminate, redundant, structures it is proposed to continue to rely on the criterion that always was the primary one, the criterion of permissible deformations; the derived, or secondary, consideration (namely, the stresses involved) is relegated to its relative position of importance; it is treated as a matter of interest, as a matter that might well help to clarify questions, but not as a matter of primary importance.

A theory is of value in direct proportion to the extent to which it covers the pertinent factors that affect the problem to which it is applied. Any important factor not included within the scope of a theory limits that theory. The theory of elasticity does not give even a hint as to why a perfectly elastic material—a material that is elastic only—is unfit for use as a structural material. The application of the theory of elasticity is thus seriously circumscribed by rules of engineering practice and by stringent specifications. While thus restricted it is open to criticism as a sound and all-inclusive philosophy of structural design.[3]

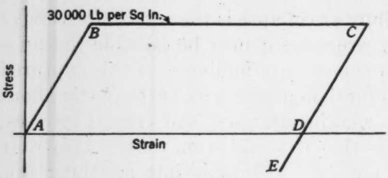

FIG. 2

Structural steel, mild steel, machine steel, open-hearth steel, low carbon steel, and iron, are the various names for the same substance. It possesses an extraordinary property graphically represented by Line *BC* of the partial stress-strain curve shown in Fig. 2. This property is designated by the engineering term "ductility," which is defined herein as the property of a material by virtue of which after behaving elastically over a considerable range of stress or strain, it can suffer relatively large deformation without appreciable change in stress. During these changes in form within the ductile range, the stresses remain essentially constant. It is important to realize that, after passing the elastic limit, the stresses are neither appreciably increased or decreased until very considerable deformation has occurred.

Although the curve of Fig. 2 may appear idealized, this is not necessarily the case to any great degree. To be sure, stress-strain curves frequently are recorded with a bulge instead of the sharp angle shown in Fig. 2 at Point *B*; or, they appear with a mild transition curve between the two straight lines meeting at Point *B*. It must be noted that the things tested are specimens and not filaments. For example, an ordinary steel bar suffers a differential stress between material in the outside and the center of the bar due to the cooling of the core (on the cooling bed) after the outside of the bar is already black and hardened. Furthermore, the rate of running the testing machine affects the curve. In other words, variations from stress-strain curves of mild steel, as shown in Fig. 2, may frequently be assigned to the test specimen rather than to the material. In several hundred tests reported in 1918[4] the writer found the horizontal part of the curve very pronounced and coincident with the proportional limit. Metallographically, an extraordinary thing happens when the elastic limit is exceeded and the ductile range begins, because it is unusual as judged from the behavior of other material. When the elastic limit is exceeded the crystal grains fail. However, in this connection failure is to be sharply distinguished from rupture. A cleavage is formed within the grain and the one part slips over the other. All this time, however, the two parts of the crystal grain cling to each other tenaciously as if connected by a very viscous glue. When a specimen of structural steel is tested in tension and strained beyond the elastic limit, to the extent indicated by Point *C*, Fig. 2, and subsequently examined, it is likely that the crystal grains in a part of the specimen will be found still intact, whereas in the other part they will be shown to have suffered permanent deformation.

---

[3] "Elastic Energy Theory," by J. A. Van den Broek, John Wiley & Son, 1931, p. 231.

In the training of engineers, the emphasis on the theory of elasticity leads to a respect for the elastic limit which sometimes borders on fear. To be sure, to exceed the elastic limit in a structure may mean disaster, but inherently it means no such thing. Only when several redundants, functioning to the same end, have each reached the elastic limit, or buckling strength, is failure imminent. Every inch of every wire in every strand of each cable of the Brooklyn Bridge in Brooklyn, N. Y., was strained cold, much beyond its elastic limit, before it was assembled and built into the bridge. This structure has stood up for more than 60 yr and is daily loaded well beyond what it was originally expected to carry. Cold-drawing, cold-rolling, and cold-stamping are processes involving the passing of the elastic limit of the material, sometimes resorted to in order to obtain a desirable shape, but more often done because of their beneficial effects on the properties of the material.

The theory of limit design is the instrument by means of which the capacity strength of a structure is computed. Its philosophy is predicated on the fact that a structure will fail only when as many members, or restraints, as the structure has redundants plus one, are loaded to their capacity strength. From this limit strength, the safe strength of the structure is derived by the introduction of an over-load factor or factor of safety.

It is proposed to present the theory by means of illustrative examples: Four examples in redundant beams referred to in order as Cases 1, 2, 3, and 4, and one example in redundant steel towers.

THEORY

In the theory of limit design the emphasis is shifted from the concept "stress" to that of "permissible deformation." In this connection three dicta of primary importance are proposed:

(1) A statically indeterminate, redundant, structure is one in which two or more members, reactions or restraints function to the same end;

---

[4] "The Effect of Cold Working on the Elastic Properties of Steel," Carnegie Scholarship *Memoirs*, Iron and Steel Inst., Vol. IX, 1918; see, also, *Engineering*, July, 1918.

(2) Sharp distinction is made between deformations of the order of magnitude of elastic deformations and deformations of the order of magnitude of ductile, or of buckling, deformations; and,

(3) When in a well designed, and especially a properly detailed, n-fold redundant structure, n redundants are stressed to their elastic limit, or up to their critical buckling load, the deformations involved are of the order of magnitude of elastic deformations until an $(n + 1)$th member has reached its elastic limit or its critical buckling capacity.

Case 1.—To find the maximum uniformly distributed load, applied in one direction and sense, that a beam built in at both ends can carry with a factor of safety of 2.—The elastic and ductile properties of the material of which the beam is made are assumed to be as represented graphically by Fig. 2. The beam is 6 ft long, fully restrained at both ends, and of rectangular cross-section, 6 in. × 2 in., as shown in Fig. 3.

The section modulus of this beam is $\frac{b\,h^2}{6} = \frac{2 \times 6^2}{6} = 12$. The maximum resisting moment that the beam can develop is:

$$M = \frac{s\,I}{c} \quad \text{..............................} \quad (1)$$

or, $M = 30\,000 \times 12$ in-lb $= 30\,000$ ft-lb.

The elastic behavior of this beam is represented by Fig. 3. From the theory of static equilibrium, the increment of bending moment between the end and middle of the beam is $\frac{w\,L^2}{8}$. The theory of elasticity is necessary, however, to tell that the ratio between M_1 and M_2 is as 1 : 2, or, in other words, that the bending moment at each end is $\frac{w\,L^2}{12}$, whereas that in the middle is $\frac{w\,L^2}{24}$.

The elastic curve presents essentially two cantilever beams, _A-B_ and _C-D_, and one simple beam, _B-C_.

To express the foregoing argument in physical terms, the beam fully restrained at both ends presents a case of two cantilever beams and one simple beam working together to the same end—that of carrying a uniformly distributed load w over the entire length of the beam. The combined task of the simple beam and the two cantilever beams is obvious. The theory of elasticity, however, is necessary to determine just how this task is distributed in simple beam action and cantilever beam action.

If no part of the beam is to be stressed beyond the elastic limit, the capacity load w that the beam can carry is $w = \frac{30\,000 \times 12}{6 \times 6} = 10\,000$ lb per ft; and the safe load, with a factor of safety equal to 2, is 5 000 lb per ft.

It is of interest to inquire into what would happen if this beam were subjected to a load greater than 10 000 lb per ft. As soon as this load is exceeded, the elastic limit in the outer fiber in a section at the wall is also exceeded. The steel at this point, which is ductile, flows somewhat in a manner indicated by Line _B-C_ in Fig. 2. The bending moment undergoes a change as indicated by the change from the dash line to the solid line in Fig. 4. The points of inflec-

tion, B and C, shift to Points B' and C' respectively (Fig. 4), and this process continues until the bending moment in the center has reached its critical value (equal to that at the wall) namely, 30 000 ft-lb, and the corresponding load on the beam has reached its critical value, w' lb per ft (Fig. 4). If loading beyond w' lb per ft is attempted, it appears that ductile deformation at both center and end of the beam continues unhindered. The deformations assume proportions of the order of magnitude of ductile deformations, and the end of the beam's usefulness is reached.

It has been stated that the theory of elasticity was necessary in order to determine the true ratio between M_1 and M_2 within the elastic range. In this instance, having determined by the foregoing argument that the capacity moments at the center and the end of the beam must be equal before disastrous results will take place, one may proceed with the arguments of static equilibrium to obtain the capacity carrying load w': $w'\dfrac{L}{2}\times\dfrac{L}{4} = 2\,M_1 = 60\,000$ ft-lb; and, $w' = 13\,333$ lb per ft.

FIG. 4.—BUILT-IN BEAM LOADED WITH ITS CAPACITY LOAD

The application of the factor of safety again is contrary to the usual practice. Instead of applying it first in order to determine working stresses, it is applied last in order to determine safe load. Thus, if the capacity load is 13 333 lb per ft, and the factor of safety is 2, the safe load is 6 667 lb per ft. This change in the order of applying the factor of safety is not the trivial matter it may seem. By applying the factor of safety immediately, the designer finds the working stress in the middle of the elastic range and is helpless in extricating himself from the difficulty. By reserving the application of the factor of safety to the last and basing his analysis upon the elastic limit stress, he is in a position to study the effects of a slight ductile flow. For working loads, the ultimate safe load will fall back well within the elastic range. This means that ductile flow will most probably never occur in the life of the structure. It would occur only in case of a 50% over-load, and even then, if a slight permanent deformation is permissible, such permanent deformation would still be of the order of magnitude of elastic deformation up to a 100% over-load.

It may be argued that when a built-in beam is loaded to full ductile capacity, the magnitude of the bending moment at the walls would be somewhat in excess of that of the bending moment at the center. This merely means that the capacity load w' is slightly in excess of the computed 13 333 lb per ft. Thus, by ignoring it and by assuming the moment at the wall to remain at the constant magnitude of 30 000 ft-lb, the argument is on the side of safety. At this stage the writer intentionally omits studying this question in detail so as to avoid spending his efforts on the study of secondary considerations and thus diverting attention from the essential arguments.

When all the fibers in one cross-section of a beam are stressed to the elastic limit, the stress-distribution diagrams over the cross-section would appear as two rectangles, and not as two triangles. In that case the resisting moment is expressed by the formula:

$$M = 2\, s_1\, \bar{y}\, A \qquad \ldots\ldots\ldots\ldots (2)$$

in which s_1 is the elastic limit stress; A is the area on one side of the neutral axis; and $\bar{y}$ is the distance to the centroid of this area. Thus, the value of the limiting resisting moment becomes greater than that given by the usual formula, Equation (1). When all fibers along one section of the beam have reached the elastic limit this value would be 50% greater in a beam with a rectangular cross-section and 6.67% greater in a C.B. 12 in. by 12 in. by 65 lb beam.[5]

Case 2.—To find the maximum uniformly distributed load, applied an indefinite number of times in one direction and in one sense.—When a ductile steel is strained beyond the elastic limit (*B-C*, Fig. 2) and then the straining effect removed, the return path of the stress-strain curve (*C-D*, Fig. 2) is essentially parallel to the initial path *A-B*; that is, the material again behaves according to Hooke's law. If care is not taken at this point, one can easily become so lost in details that essentials are overlooked. As to whether or not Curve *C-D*, Fig. 2, is parallel to Line *A-B* depends primarily on the time that is allowed to elapse between the moment the over-strain is completed and the moment the straining effect is removed.[4] Furthermore, when the stress is completely released, and then reversed, the material continues to behave elastically as indicated by Line *D-E*, Fig. 2. To assume Line *C-E* in Fig. 2 to be a straight line is not exactly true, but by assuming conditions that would prevail ultimately if sufficient time elapses, conclusions are reached which, in certain cases, argue against the adoption of the theory of limit design (see Case 3). These conclusions, however, are on the safe side.

---

[5] See a dissertation, by E. O. Scott; presented to the University of Michigan in 1939, in partial fulfillment of the degree of Doctor of Philosophy.

If the load of 13 333 lb per ft, in Case 1, Fig. 3, is removed, the beam behaves elastically. The stresses return toward zero and in certain points may pass through zero and reverse. The elastic behavior of a beam under a negative load of 13 333 lb per ft is represented by Fig. 5. The final condition of the beam under a positive load of 13 333 lb per ft is represented by Fig. 4. When the free-body sketch of Fig. 5 is superimposed on the free-body sketch of Fig. 4, the result is a free-body sketch of the beam with the load removed (see Fig. 6). When the bending moment of Fig. 5 is superimposed on the bending moment of Fig. 4, the result is as demonstrated in Fig. 6, which shows the residual bending moment left in the beam after it had been loaded to full-capacity ductile load and after this load had been removed.

The conclusions to be drawn from the foregoing appear interesting and important. What would happen if a structure is loaded beyond the elastic limit? This question is introduced not because it is actually proposed ever, consciously, to permit it, but to find a better engineering philosophy than the one based on the consideration of working stresses. It must be kept in mind that after the capacity load is found the safe load is derived from it, and stipulated to be a safe margin below the capacity load. It is seen that a capacity ductile load induces deformations of the order of magnitude of elastic deformations. A removal of the capacity load leaves the structure with a slight permanent set, and, what is more important, with a residual stress condition set up in it. If the full capacity load is again applied in the same direction and sense, the behavior is completely elastic. For example, under completely elastic behavior the bending moment of a beam, loaded as shown in Fig. 7, develops bending moments of 20 000 ft-lb at the center and 40 000 ft-lb at the wall. When this loading and these moments are superimposed upon the residual loads and moments, represented by Fig. 6, the resultant loads and moments are those shown in Fig. 4, this time, however, obtained elastically. This means that for an application of one type of limit loading, up to ductile capacity, the

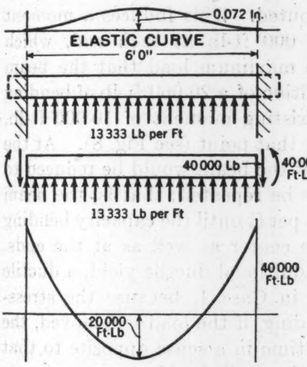

Fig. 5.—Restrained Beam Loaded Elastically in a Negative Sense

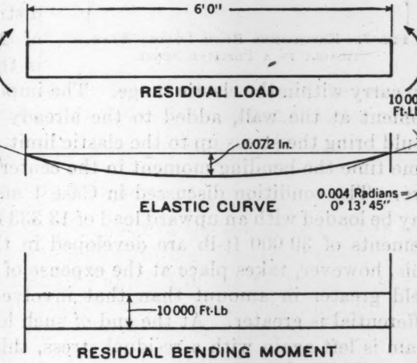

Fig. 6.—Built-in Beam After Removal of Limit Load

first application and removal of the load induce in the structure residual stresses of such nature and magnitude that subsequent application of loads does not call forth additional ductile deformation. After the first application of the loads the behavior of the structure thenceforth again becomes completely elastic.

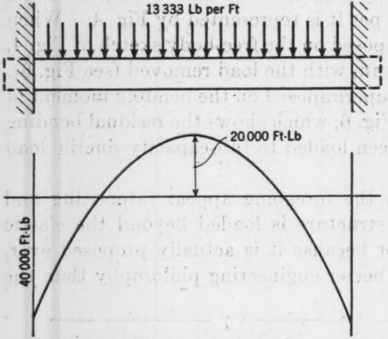

FIG. 7.—RESTRAINED BEAM LOADED ELASTICALLY IN A POSITIVE SENSE

Case 3.—To find the maximum uniformly distributed load applied an indefinite number of times in one direction, but in alternating sense (complete reversal of load), which the beam can carry with a factor of safety of 2.—Beginning with the residual stress condition of Fig. 6: A load of 6 667 lb per ft is applied in the upward direction, uniformly distributed. This induces a moment of 20 000 ft-lb at each end, which is the maximum load that the beam can carry within the elastic range. The imposition of a 20 000 ft-lb of bending moment at the wall, added to the already existing moment of 10 000 ft-lb, would bring the stress up to the elastic limit at that point (see Fig. 8). At the same time the bending moment in the center of the beam would be reduced to zero. The condition discussed in Case 1 may be repeated; that is, the beam may be loaded with an upward load of 13 333 lb per ft until the capacity bending moments of 30 000 ft-lb are developed in the center as well as at the ends. This, however, takes place at the expense of additional ductile yield, a ductile yield greater in amount than that involved in Case 1, because the stress-differential is greater. At the end of such loading, if the load is removed, the beam is left again with a residual stress, this time in a sense opposite to that shown in Fig. 6. If, next, a downward load is applied, this process repeats itself. Each time, however, additional ductile strain is involved. Each strain may be of the order of magnitude of elastic strains. A relatively few repetitions, however, will make the addition of these strains objectionable and dangerous. This phenomenon is not to be likened to what is commonly understood by fatigue. This is not a question of thousands or millions of repetitions of load but rather a question of, perhaps, a dozen repetitions or so. What happens may more aptly be likened to a wire nail held in a vise and bent back and forth, each time assuming a permanent set until, in comparatively short time, it breaks.

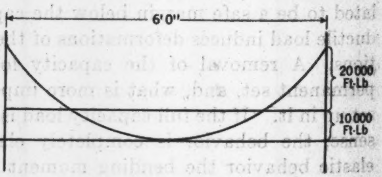

FIG. 8

If the foregoing arguments are applied to a reversal of load, smaller than the capacity ductile load but greater than the most severe load within the elastic range (say, a reversal of a load of 11 000 lb per ft), then it develops that each application of the load in opposite sense leaves residual stresses of a sense favorable to a load such as that last applied, but unfavorable to a load of a sense opposite to that last applied. The permanent sets would be smaller in magnitude, but would nevertheless be accumulative. There seems no other alternative, then, but to conclude that, if a complete reversal of stress is possible, the elastic limit is again the final criterion of strength. The saving feature of this argument lies in the circumstance that, in bridges and in steel frames, partial reversal of stress is comparatively rare, and complete reversal of stress is so rare as to be almost non-existent. (To avoid disastrous results under a complete reversal of loading the sum of the positive and negative loadings must not exceed an amount equal to twice the maximum elastic loading. Thus the beam in this example will sustain an indefinite application of an 11 000 lb per ft positive load and a 9 000 lb per ft negative load, or a 12 000 lb per ft positive and an 8 000 lb per ft negative loading.)

This phenomenon of residual stresses and accumulation of ductile deformations is of primary importance in the theory of limit design. Accumulation of ductile deformation may occur under moving loads even when no reversal of loads takes place.

Case 4.—To find the maximum (limit) value of two concentrated loads, P_5, spaced 10 ft apart, that can be moved an indefinite number of times along a beam of two spans, each 10 ft long, and of section modulus, $\frac{I}{c}$, equal to 30.—It is proposed to discuss this case in four steps:

(*a*) Find the single limit load P_1 applied in the center of the left span, and the residual moments and reactions resulting from that load;

(*b*) Find the double limit loads P_2 applied in the center of each span simultaneously, and the residual moments and reactions resulting from them;

(*c*) Find the limit loads P_3 that may be applied alternately: Singly in the center of one span, or simultaneously in pairs, at the center of both spans; and,

(*d*) Find the limit loads P_4 that may be moved along the beam an indefinite number of times.

Step (*a*).—Fig. 9(*a*) shows the capacity load, concentrated in the center of one span, that the beam can carry without exceeding the elastic limit; Fig. 9(*b*) shows the limit load P_1 concentrated in the center of one span; and, Fig. 9(*c*) shows a negative loading of magnitude equal to P_1 when the beam behaves altogether elastically, the loads and reactions being in direct proportion to those of Fig. 9(*a*). As previously stated, if the limit load P_1 (Fig. 9(*b*)) is removed, even if the maximum concentrated loading within the elastic range is 36 923, the effect is the same as if a negative elastic loading (Fig. 9(*c*)) is superimposed upon the loading shown in Fig. 9(*b*). The material then behaves elastically as represented by Line *C D E* (Fig. 2). Fig. 9(*d*) represents the residual reactions and moments when the loading in Fig. 9(*c*) is superimposed upon the loading in Fig. 9(*b*); that is, when Load P_1 of Fig. 9(*b*) is removed.

As a check of the loading and moment shown in Fig. 9(*b*), reverse the loading represented in Fig. 9(*c*) and superimpose it upon the beam in Fig. 9(*d*). This is a case similar to the one discussed in detail under Case 2.

Step (*b*).—The arguments for Step (*b*) on the basis of Fig. 10 are similar to those previously advanced in connection with the representations of Step (*a*) on basis of Fig. 9. The capacity limit loads P_1 and P_2, in each instance, are 45 000 lb. After they were once applied they could each be applied an indefinite number of times and the behavior of the structure would be perfectly elastic with each subsequent application of the loading.

FIG. 10

Step (*c*).—However, if the loading P_2 represented by Fig. 10(*b*) is applied after the loading P_1 (Fig. 9(*b*)) had been previously applied and removed, it

would meet with a residual loading condition (Fig. 9(*d*)) which is responsible for an initial bending moment over the middle support of 33 000 ft-lb. Thus the elastic limit over the middle support is reached sooner than it is in the case represented by Fig. 10(*b*), in which the loading presumably started from a zero base line. This would therefore result in ductile flow of somewhat greater intensity than that noted in the case given in Fig. 10(*b*). If subsequently the P_2-loading is removed and the P_1-loading is again applied, a similar situation results. As the P_1-loading is applied it meets with an initial positive bending moment of 4 690 ft-lb at the middle of the left span. This in turn requires more ductile flow before the full limit load of P_1 (Fig. 9(*b*)) can be carried. Each successive application of a P_2-loading, after a P_1-loading has first been applied and removed, is seen to require additional ductile flow which, in turn, would spell disaster.

The value of P_3, the limit load which can be applied singly at the center of one span, in pairs at the center of both spans, and applied alternately an indefinite number of times, may be computed as follows:

It will be recalled that, so far as repetitions of limiting loads are concerned, in accordance with the theory of limit design (Case 2), the structure is left with a residual load in a pre-stressed state, as the result of over-strain. This residual loading may be beneficial, if not too large, and if not of the wrong sign. In the case of repetitions of the same load (Case 2) the residual stresses are always the maximum and of the correct sign, thus making it possible for subsequent limit loading to take place entirely within the elastic range. When there is complete reversal of limit loading (Case 3) the residual loading is of the wrong sign, thus making the theory of limit design inapplicable for practical purposes. In the case of alternate loading (the loading shown in Fig. 9(*b*), alternating with the loading shown in Fig. 10(*b*)) the residual loading may well be too large. This does not mean, however, that a smaller residual loading could not be beneficial.

The largest possible values for the residual loading can be computed so that, with a design based upon that value, the beam will be stressed alternately to full capacity—first stressed to full capacity at the center of the span, and then stressed to full capacity over the middle support, without, however, resulting in further ductile flow, or over-strain. From the study of Fig. 9(*a*) the maximum moment in the center of the span is known to be $\frac{13}{64} P L$. Fig. 10(*a*) shows that the maximum moment over the middle support is $\frac{12}{64} P L$. The ideal residual bending moment would be the dash line in Fig. 11, so defined that the ordinate, measured from the dash line as a base to the point marking the maximum moment in the center of the span, shall equal the ordinate measured to the point marking the maximum moment over the middle support. If the distance to the vertex of the residual bending moment diagram is represented by x,

$$\frac{13}{64} P_3 L - \frac{x}{2} = \frac{12}{64} P_3 L + x \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

and, $x = \frac{1}{96} P_3 L$. The limiting bending moment is 75 000 ft-lb; and, therefore, $\frac{12}{64} P_3 L + \frac{1}{96} P_3 L = \frac{19}{96} P_3 L = 75\,000$ ft-lb; or, $P_3 = 37\,895$ lb. The answer is given in five significant figures, not because the writer is of the opinion such accuracy is justified in this instance, but because it may be of interest, if any one should be so inclined, to substitute the value of 37 895 lb for the 36 923 lb in Fig. 9 and compute the residual reactions and moments. Then repeat the argument of Step (*c*) with the value 37 895 lb substituted for 45 000 lb. It will be found that the alternate loading with this value of P_3 remains exactly within the elastic range.

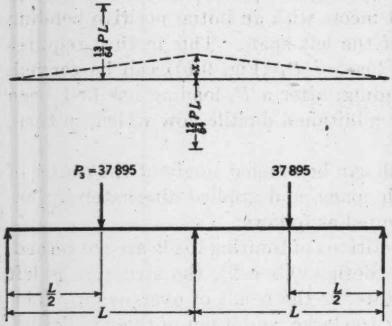

FIG. 11

In the case of moving loads, a similar procedure may be followed.[6] Suppose a single load, P_4, rolls along the beam. The maximum negative bending moment will be at the middle support. It will occur when Load P is at the distance 0.42265 L from the middle support and when it is of the magnitude 0.096225 $P L$. The maximum positive moment in both spans of the beam is expressed by the equation:

$$M = (2 L^3 x + L^2 x^2 - 4 L x^3 + x^4) \frac{P}{4 L^3} \ldots\ldots\ldots\ldots (4)$$

x being measured positive to the left from the middle support. The value of the maximum negative moment as well as the graph giving the maximum positive moment is represented in Fig. 12.

If it is assumed that the magnitude of P_4 is very small to begin with and that it becomes progressively larger with each passage along the beam, the elastic limit in positive bending will be reached and a residual stress built up favorable to the application of loads of the same magnitude subsequently applied. If the load P_4 is quite large the resulting over-strain will cause the residual loading, although favorable to the positive moments, to become unfavorable to the negative moment over the support. This is explained in Case 4, Step (*c*). The most favorable residual bending moment is the one represented by the dash line in Fig. 12. It may be found graphically by drawing the dash line so that the maximum positive ordinate shall equal the maximum negative ordinate. For the purpose of this paper the solution has been found analytically instead of graphically. It is found that the maximum moment equals 0.1744 $P_4 L$. Equating this moment to 75 000 ft-lb and solving for P_4, as was explained in Case 4, Step (*c*): $P_4 = 43\,000$ lb. It is to be noted that the maximum positive ordinate, measured from the dash line, does not occur in the center of the span. The physical meaning is as follows: When a load of 43 000 lb passes over the beam for the first time, it causes over-strain and builds up residual reactions and moments. These residual reactions and moments are of a magnitude such that, during subsequent passages of the load P_4 (43 000 lb), the beam behaves entirely elastically. The elastic limit stress will be reached at both the point of maximum positive bending and that of maximum negative bending; but this elastic limit stress is not exceeded. The safe load, on the basis of a safety factor of two, would thus be one-half of 43 000 lb, or 21 500 lb.

[6] "Über die Bemessung Statisch unbestimmter Stahltragwerke unter Berücksichtigung des Elastisch-Plastischen Verhaltens des Baustoffes," by Hans Bleich, *Bauingenieur*, 1932. Heft 19/20, p. 261.

Step (*d*).—Suppose that a number of loads, each of magnitude P_5, and 10 ft apart, roll along the beam. As the loads first come on, only one span will be loaded with a single load. The curve for maximum positive moment (Fig. 13), therefore, will be identical with the curve shown in Fig. 12. The maximum negative moment, however, will occur when the load P_5 is in the center of each span. This maximum negative moment will be $0.1875\ P_5\ L$.

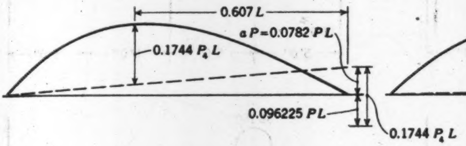

FIG. 12

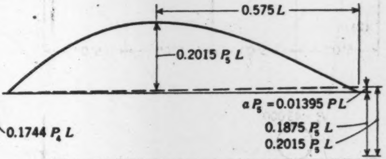

FIG. 13

The residual bending moment that would permit perfectly elastic behavior for an indefinite number of load applications, without resulting in additional over-strain, is again shown by the dash line. An analytical solution gives the value for the equal positive and negative moments as $0.2015\ P_5\ L$. The value of P_5, which would build up this ideal residual moment, is obtained from the equation, $0.2015\ P_5\ L = 75\ 000$ ft-lb; or, $P_5 = 37\ 231$ lb.

Fig. 14 shows the results of the foregoing discussion arranged in a manner convenient for easy comparison. Fig. 14(*b*) shows the maximum loads the beam can carry without any part of the beam being stressed beyond the elastic limit. Fig. 14(*a*) shows the limit loads the beam can carry under similar conditions of loading and in accordance with the theory of limit design. The first application of the load would build up residual stresses that would thereafter insure perfect elastic behavior, provided the limit loads are never exceeded. Sketches (1), (2), (3), and (4), Fig. 14, represent loads applied only at the points shown; and, Sketches (5), (6), (7), and (8), Fig. 14, represent moving loads.

DESIGN OF A STEEL TOWER

Fig. 15(*a*) represents the upper three panels of a steel tower, the general, over-all, dimensions of which suggest a transmission tower. A transverse concentrated capacity load of 60 000 lb is assumed to be applied at Point *A* at the top of the tower. This load is purposely assumed rather large (about four times the value of a similar load on a representative transmission tower) because it is proposed to design this tower with only readily available data.

It is desirable to avoid the unusually small structural members commonly used in transmission tower design, the properties for which would not be easily available to any one inclined to check this design. Therefore, in this design, all structural members are limited to angle-irons of equal legs. The slenderness ratio is limited to 200; and the joints are assumed welded instead of riveted, or bolted, so that the question of punched, or reamed, holes is eliminated. This, then, does away with the uncertainty as to how much to reduce the cross-section area in tension due to the presence of the holes. The stiffening effect of the welded joints and the resulting moments are ignored, which is in agreement with practice and is on the side of safety. The buckling strength of the compression members is computed on the basis of Euler's formula,

(*a*) LIMIT LOADING

(*b*) LOADING WITHIN ELASTIC RANGE

FIG. 14.—ELASTIC LIMIT STRESS IS 30 000 POUNDS PER SQUARE INCH; AND, SECTION MODULUS IS 30

$$P = \frac{\pi^2 EA}{\left(\frac{L}{r}\right)^2} \dots\dots\dots\dots\dots\dots\dots\dots (5)$$

The tower is to be designed symmetrically with reference to the center line.

It must be kept in mind that the purpose of this paper is to discuss and illustrate the theory of limit design. In listing the foregoing specifications for tower design the writer is guided solely by the one consideration, that his work shall lend itself to convenient and independent checks. It is not to be assumed, therefore, that he means to express a preference for Euler's formula over some other column formula; nor that he wants to be considered as committed to the feasibility of welding transmission towers in the field. The restriction to equal-leg angles is equally arbitrary and would of course have no merit in a practical case.

FIG. 15.—DESIGN OF A STEEL TOWER

As indicated near the beginning of Case 1, the sum of the moments at the wall and in the center of the beam is $\frac{w\,L^2}{8}$. This conclusion was reached on the basis of the theory of static equilibrium. Any other theory applied to the problem is supplementary. On the basis of the theory of elasticity it was found that the ratio of the two moments is 2 : 1. On the basis of the theory of limit design it was held that, before failure could occur, the ratio between the two moments became 1 : 1.

Similarly, whether the theory of elasticity or the theory of limit design is used in the design of the tower represented by Fig. 15(*a*), either theory is only supplementary to the theory of static equilibrium. In any case the forces around Joint *A* are in equilibrium and their force diagram must close. The same is true about the forces around Joint *B*. Qualitatively, these respective force diagrams appear as shown in Fig. 15(*b*) and 15(*c*). Since F_a, the force in Member *a*, occurs in both force diagrams, the two may be superimposed to appear as in Fig. 15(*d*). An infinite number of force polygons for the joints at both Points *A* and *B* are possible. It is significant that one of the limiting conditions is to the effect that they have the force F_a in common.

In an analysis on the basis of the theory of elasticity dimensions are assumed for the members of the tower, and the stresses are computed, being careful not to allow the stress in any of the members of the tower to exceed the safe working stress. Furthermore, the designer must also make certain that the computed stresses generally are not unreasonably low. If one or the other of these conditions cannot be satisfied, some member (or members) of the structure is changed and the analysis repeated.

An analysis on the basis of the theory of limit design begins by assuming the dimensions of one member and proportioning the neighboring members in relation to it. The choice of sizes of members is limited by those commercially available, and the result of the theory is limited by the available theory of capacity strength of either the compression or tension members. These two limitations apply to any conceivable theory one might use, and they detract from the theory of limit design no more than they detract from the theory of elasticity. With these two limitations in mind, one might design the tower in the manner of the "one hoss shay," so that, when it collapses, it will collapse by failure of all its component parts simultaneously.

Consider the top panel (*A B C D*, Fig. 15(*a*)) of the tower. If Strut (*a*) were made extremely light, Triangle *B C D* would become relatively ineffective and the compression member *C* would have to be made extra heavy. On the other hand by making Strut (*a*) heavy and the compression member *C* light, the work of carrying the load would be thrown on Triangle *B C D* and Bar *d* would have to be made heavy. Either procedure is undesirable and is contrary to the specification that the tower is to be designed symmetrically relative to the center line. This calls for equal sizes of Members *c* and *d* and it is desirable that both be loaded as nearly as possible with their maximum safe load.

For Bar *a*, connecting Points *A* and *B* (Fig. 15(*a*)), select a $3\frac{1}{2}$ in. by $3\frac{1}{2}$ in. by $\frac{1}{4}$ in. angle-iron. Its buckling capacity strength would be (by Equation (6)): $\frac{9.87 \times 30\,000\,000 \times 1.69}{104.3^2} = 46\,000$ lb. It can develop this strength only on condition that the other members of the panel, of which Bar *a* is a part, are capable of developing proportional strength. That is, if (Fig. 15(*d*)) a force equal to 46 000 lb (see Fig. 15(*d*)) is laid off to represent the force in Bar *a*, then Bars *c* and *d* must be capable of developing forces at least equal to the magnitudes marked *c* and *d* in the force diagram (Fig. 15(*d*)).

The effective length of Diagonal *c* is measured from the point of intersection of the diagonals to Point *D*. While one of the diagonals is in compression the other is in tension, and since they are supposedly connected at the point of intersection, the tension diagonal restrains the compression diagonal. This effective length of Member *c* scales 80 in. A 3 in. by 3 in. by $\frac{1}{4}$ in. angle for Diagonal *c* would develop a capacity buckling strength of 23 200 lb. Since the force vector *c* (Fig. 15(*e*)) scales only 20 000 lb this angle would be satisfactory. However, the force vector *d* (Fig. 15(*e*)) scales 65 000 lb. The capacity strength of a 3 in. by 3 in. by $\frac{1}{4}$ in. angle in tension is only 1.44 × 30 000 lb = 43 200 lb. This size of angle for the diagonal *d* would thus be insufficient. A 3 in. by 3 in. by $\frac{3}{8}$ in. angle, with an area of 2.11 sq in., could develop a capacity tensile strength of 63 300 lb. Except for the stipulation of symmetry the use of this angle could be justified as follows: The force vector *c* could be moved parallel to itself until it reached a value equal to the 23 200-lb capacity strength of Diagonal *c*, as shown by the dash line in Fig. 15(*e*) (Diagonal *c* being 3 in. by 3 in. by $\frac{1}{4}$ in.). In that case it appears that the diagonal *d* would have to carry only 61 800 lb, and that the 3 in. by 3 in. by $\frac{3}{8}$ in. angle is large enough for that purpose. If there were a greater choice of commercial sizes one could select a still smaller angle for Diagonal *d*—one capable of developing a capacity tensile strength of only 61 800 lb. If the top panel of the tower had been thus designated, that panel would fail in the two diagonals before failing in Strut *a*.

Since the designer is restricted by a specification demanding a symmetrical structure he could, of course, also change the diagonal *c* to an angle, 3 in. by 3 in. by $\frac{3}{8}$ in. This appears wasteful, making some other solution desirable.

If, for Bar *a*, he selects an angle 3 in. by 3 in. by $\frac{5}{16}$ in., which has a capacity buckling strength of 35 400 lb, he obtains, for the forces around the Joints *A* and *B*, the force diagram shown in Fig. 15(*f*). A 3$\frac{1}{2}$ in. by 3$\frac{1}{2}$ in. by $\frac{1}{4}$ in. angle iron, instead of Bar *c*, with an effective column length of 80 in., will develop a buckling strength of 37 200 lb and a capacity tensile strength, instead of Bar *d*, of 50 700 lb. In each case this is a little more than required. The advantage in changing from a design based on Fig. 15(*e*) to one based on Fig. 15(*f*) is greater than the saving in weight of Bars *a*, *c*, and *d* would imply. For the stress distribution in Bars *a*, *c*, and *d*, as shown in Fig. 15(*f*), the compressive force to be carried by Member *e* (Fig. 15(*f*)) scales 38 000 lb. Its effective length is 109 in. A 4 in. by 4 in. by $\frac{5}{16}$ in. angle will just develop a buckling strength equal to 38 000 lb. The same angle in the place of Member *b* will develop a tensile capacity load equal to 72 000 lb, which is almost double the required capacity. However, the design of Bar *e* is the controlling consideration.

By strictly analogous processes, a force diagram may be drawn for the entire tower that will satisfy only the conditions of static equilibrium (Fig. 15(*f*)). Any continuous force diagram, and one that closes, may be regarded as satisfactory. The members of the tower are to be so selected that their capacity strength, either in compression or tension, as the case may be, will be greater than the value of the corresponding force indicated on the force diagram. In that manner the capacity load of the tower is obtained. If the tower is to be designed for an over-load capacity, say, of 100% (in other words, with a factor of safety of two), begin by multiplying the load for which the tower is to be designed by this over-load factor. Continuing thus, design the structure, and upon completion obtain the safe load by dividing the capacity load by this same over-load factor.

Comment on Steel Tower Design.—A few generalizations at this point would seem to be of interest. Figs. 15(*d*), 15(*e*), and 15(*f*) demonstrate that the forces in Members *c* and *d*, in each case, add up to the same value, 85 000 lb, which is equal to the distance graphically represented by the diagonal 2–3 (Fig. 15(*f*)). This is a geometric proposition, true for any parallelogram with sides parallel to the diagonal bracing *c* and *d* (Fig. 15(*a*)) that may be drawn within the isosceles trapezoid 1–2–3–4 (Fig. 15(*f*)). Taking advantage of this fact, one may scale the distance 4–5 (Fig. 15(*f*)) and find it equal to 68 300 lb, thus concluding that the diagonal-bracing in Panel C D E F (Fig. 15(*a*)) must carry this load. Next, select from available commercial stock, the smallest angle-irons, of which the combined capacity strength in tension and compression is at least equal to 68 300 lb. The effective length of the compression member *h* scales 135 in. The capacity buckling strength of a 4 in. by 4 in. by $\frac{1}{4}$ in. angle, 135 in. long, is 19 800 lb. Its capacity strength in tension is 58 200. The combined capacity of the two angles acting in the place of *h* and *j* (Fig. 15(*a*)), therefore, would be 78 000 lb. This is somewhat in excess of the required value, but, limited as he is by available commercial sizes, it is the closest approximation the designer can achieve. The next step is to lay off the full value of 19 800 lb (Fig. 15(*f*)), as this has a tendency to reduce the value of the compressive forces in Member *f* as well as in that of Member *k* (Fig. 15(*f*)).

The individual force polygon for the various members acting at each joint may be found in Fig. 15(*f*), which shows that the force required to be carried by the diagonal bracing *n* and *r*, in the bottom panel, scales 40 000 lb. The effective length of the compression diagonal *n* scales 144 in. A 3 in. by 3 in. by $\frac{1}{4}$ in. angle would develop a capacity tensile strength of 43 200 lb whereas its slenderness ratio is $\frac{144}{0.59} = 244$. According to the specifications a column with a slenderness ratio greater than 200 is not permitted; or, if used, is not to be considered as carrying any load. The tension diagonal *r*, therefore, is assumed to carry the full required load of 40 000 lb, which it is capable of doing. The functioning of the diagonal bracing in the bottom panel is in agreement with engineering practice as applied to the bracing of the center panel in highway bridges. In these bridges it has generally been the practice to brace the center panel with two light diagonals capable of carrying only tension. While one of the diagonals is loaded in tension the other is assumed to carry no load whatsoever. This is another instance of the theory of limit design being applied in an isolated case.

It may be observed (see Fig. 15(*f*)) that the higher the value one can assign to the compression members *c* and *h* the smaller will be the value of the forces in the compression members *e*, *f*, *l* and *k*.

If the values of the forces carried in Members *c* and *h* could be stipulated to be equal to those in Members *d* and *g*, respectively, the parallelograms *cd* and *hj* would appear as perfect "diamonds." They would be symmetrical to the center line of Fig. 15(*f*), and the force, Distance *f*, which now scales 13 000 lb, would be zero. In that case the cross brace *f*, between Points *C* and *D*, could be omitted.

There are two ways in which this object could be accomplished. Members *c* and *h* could either be designed heavy enough to carry one-half the diagonal bracing load, or more cross bracing could be introduced, thus reducing the effective lengths of *c* and *h*, so that their slenderness ratio would become less than 100. Either of these designs would be more costly than one including the cross braces *f* and *l*.

If the foregoing conclusions are compared with those dictated by the theory of elasticity, it is clear that, by no stretch of the imagination, can there be a larger force in Member *d* than in Member *c*. In order to avoid complications, consider only the top panel and assume the distance *C–D* to remain unaltered. Only if Member *a* were infinitely stiff would Points *C* and *D* carry the same load. With an angle-iron of ordinary proportions acting in the place of *a*, the load in Member *c* is certain to be larger than the load in Member *d*. The writer offers no objection to these conclusions; he objects only to making them a basis for design. Without computing exactly what the stress in Member *c* would be under the theory of elasticity, one needs to conclude only that it would be greater than half the sum of 50 000 lb and 35 000 lb—that is, greater than 42 500 lb. The stipulated angle ($3\frac{1}{2}$ in. by $3\frac{1}{2}$ in. by $\frac{1}{4}$ in.) would not carry this load; and thus, on the basis of the theory of elasticity, the member *c* would have to be made heavier, and therefore more costly. The theory of limit design takes account of the fact that, as the capacity load is applied to the tower, the member *c* bends out somewhat as it continues to carry load, but it refuses to carry more than its own capacity load. From the time that the capacity load in *c* is reached the member *d* assumes the burden of taking care of the load increments until its capacity strength also is reached. Only then may one look for serious results. Since the tower is supposed to be designed for an over-load capacity of, say, 50% or 100%, the working load permitted is 40 000 lb (or 30 000 lb instead of 60 000 lb) and thus limited this buckling does not occur although it would do no harm if it did.

The theory of elasticity, presumably, defines all stresses within the elastic limit and no stresses in the range of capacity loads. The theory of limit design defines no stresses within the elastic limit and is the only theory that offers some definition of conditions under capacity loads. Since, in reality, it is the capacity load that a structure can carry which should govern as a basis for design, the theory of elasticity fails where the theory of limit design serves as a sound philosophy and guide.

DESIGN OF RIVETED CONNECTIONS

The study of rivet connections is especially important in connection with a proper estimate of the theory of limit design. Consider for example Fig. 16. According to the theory of rivet design, in the space between the two rivets toward the right, the upper plate would carry one-fifth of the load, whereas the lower plate carries four times as much. It is to be remembered that, although the universal application of the theory of elasticity is seriously challenged, the assertion that a material like steel is almost ideally elastic, up to a certain stress, is not questioned at all. The ratio of 1 : 4 between the stresses in the upper and lower plates is obviously inconsistent with the fact that the distance between rivets in these plates is the same. According to the theory of elasticity the two outer rivets would carry the major part of the load and the three inner ones would practically be "duds." An interesting point is that up to a certain load unquestionably this circumstance would prevail. Nevertheless, the theory of elasticity fails as completely in the design of rivet connections as it does in the analysis of many other redundant structures.

Rivet connections appear to be "giving ground" to welded joints. It may be hoped that they soon will disappear entirely. Nevertheless, they have been designed in vast numbers for many years past and the simple rules of design have been proved very satisfactory. Eminently satisfactory results must be rooted in a satisfactory and sound theory. This theory is the theory of limit design. The pity is that it has been so extensively practiced, yet so little talked or written about. A rivet connection of purely elastic material is as impossible to conceive as the punching of holes into cold glass plates and riveting them together with glass rivets. If the material were purely elastic, and nothing but elastic, the theory of elasticity would apply. Provided a riveted joint, of purely elastic material, such as shown in Fig. 16, could be made, the outer rivets would carry nearly all the load. When they fail the next two inner rivets would take the load over, and finally the center rivet would be stressed with the full load. The entire process no doubt would be completed in a very small fraction of a second; but, the failure would nevertheless be progressive.

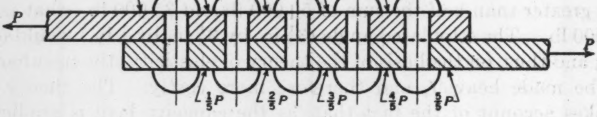

FIG. 16

The saving feature of rivet connections does not derive from the theory of elasticity, but is found in the most rigid specification which stipulates that the most ductile of steels be used. The philosophy which underlies and justifies the proved practice is the theory of limit design. According to this theory the distribution of stress in rivets is at first in agreement with that given by the theory of elasticity. As the load gradually increases, the outer rivets (Fig. 16) reach their elastic limit. They then yield slightly while they continue to carry a constant load, and only then are additional increments of the loads transmitted to the inner rivets. The structure as a whole will not fail until all rivets have passed their elastic limit. In other words, for ordinary loads, the stresses in rivets may not approach within a thousand per cent of what the theory of design indicates. The point is that the only stresses which really interest the designer are those under failing loads, and the theory of limit design teaches that for capacity loads, provided the material is ductile, the assumption of equal distribution of loads over all rivets is justified.

It is not to be thought that the problem of rivet connections is discussed at length because it offers an ideal example of the application of the theory of limit design. It is, in fact, a very poor illustration. The theory of limit design presupposes that the first redundant member in a structure that reaches its capacity strength will yield sufficiently, under a constant force, to permit other redundants to be taxed to their full capacity strength before complete failure can take place. The potential yielding of one rivet under capacity load is, after all, limited. The reason the practice in connection with the design of rivet connections is here submitted as a practical example of the application of the theory of limit design is that, for practical purposes, the theory of elasticity fails completely. The very simple rules that have governed rivet design for years have been proved to be reasonably satisfactory. If their use is to be philosophically justified, the arguments derived from the theory of limit design are the only ones that can do so. When it is argued (as is done with renewed emphasis since the appearance of the British Report of the Steel Structures Research Committee of 1931 to 1936[7]) that long rivet connections are to be avoided, this argument, again, follows directly from considerations of the principles of limit design.

PRACTICAL APPLICATION

In 1914 the writer designed a steel trestle for a three-track railway in Canada. The outbreak of the World War delayed the project and when it was reviewed again, other designers revised the plans in reinforced concrete, recommending a structure similar to that of Fig. 15(*a*) but, naturally, without diagonal bracing. The writer was told that his design of the structure was unquestionably correct, but that it was designed according to no theory at all. In fact, the structure was designed according to the best theory available. The capacity restraining moments at all the corners had been computed and from this the strength of the entire structure was determined. When this strength proved sufficient the design was approved. The interesting psychological point would seem to be the unwillingness to dignify as a theory a philosophy that ran counter to the established theory of elasticity. This attitude still appears to be very common and is giving way but slowly.

Another tale, for the truth of which the writer cannot vouch, but which sounds very plausible, is as follows: A final authority on office building design was asked what he did when a complicated analysis of wind stresses was submitted for his approval. His reply is reported to have been that he locked himself in his office, computed the safe resisting moments at top and bottom of columns and that of their connections to the floor beams in any one story, and compared them with the increment of moment from floor to floor (that is, the total wind load above the floor in question multiplied by the story height). If the former exceeded the latter, he would approve the design. This, to the writer, appears to be a sound procedure; but why lock the door? In fact, the writer questions whether there is any theory of wind stresses superior to this one.

---

[7] See, for example, Second Rept. of the Steel Structures Research Committee, Dept. of Scientific and Industrial Research; published by His Majesty's Stationery Office, London, England, 1934.

The theory of limit design has been applied to riveted connections as long as there have been rivets. The writer was aware of its being applied successfully to reinforced concrete structures on the Canadian Pacific Railway as long ago as 1914. In his own teaching of the elastic energy theory, the writer has always ended the course with a discussion of "The Limitations of the Theory of Elasticity."[8]

With reference to the application of the theory of limit design to towers it is of interest to cite two contradictory viewpoints. In 1932, Hans Bleich[9] stated that, in order to be effective, all compression members must be so proportioned that the stresses induced (including residual stresses) would never reach the buckling limit. Therefore, according to Bleich, the theory of limit design should never be applied to trusses.

On the other hand, Prof. N. C. Kist has held[10] that "every assumption of statically indeterminate values is correct if the dimensions of the structure are designed accordingly." Furthermore, he is undoubtedly responsible for the statement[11] that, "as a rule, the engineer need not apply the theory of elasticity in order to assign values for statically indeterminate quantities leading to an efficient and economical design."

The difference expressed in the foregoing viewpoints is significant. Contrary to Bleich's dictum, the writer has shown that a genuine economy, of time and material, is inherent in the theory of limit design as applied to trusses. The fear of buckling often appears deeply ingrained. This fear is fully justified from the standpoint of the theory of elasticity, or when statically determinate structures are involved. In the analysis of redundant structures a slight buckling (only enough to permit some other detail to function to its full capacity strength) need not be feared.

Professor Kist's dictum sounds sweeping but it is fully justified as long as complete reversals of capacity loads are guarded against.

CONCLUSION

The foregoing examples of the practical application of the principles of limit design are relatively few. It is believed, however, that practices essentially similar to the principles treated in this paper are commonly applied; yet the leaders in the profession, the writers of textbooks on strength of materials and theories of design, to the writer's knowledge, have consistently avoided the subject. In most of the writings on plasticity, even when the writer has ductility in mind, its application to the theory of design is ignored. Those who have written on the subject and shown its relation to problems in design are Kazinczy

[11] Explanatory notes accompanying Specifications of the Royal Society of Engineers of the Netherlands, 1933, Art. 2, p. 20.

(1914),[12] Kist (1917),[13] and Bleich (1932), and, in the United States, Edward Godfrey,[14] M. Am. Soc. C. E. A number of papers on the subject appear in the report of the Second Congress of the International Association for Bridge and Structural Engineering, Berlin-München, October, 1936. Notable among these is a paper by H. Maier-Leibnitz.

The dominance of the theory of elasticity has resulted not only in an over-emphasis of the idea of "stress," but is also responsible for the fact that most published test data are given only in so far as stresses and deformations within the elastic limit are concerned. For example, numerous test results are available on columns. Such results give the buckling loads but very little or no information in regard to the load-deformation relationship after the buckling has begun. Since this is the type of information in greatest demand relative to the theory of limit design, a vast field for experimentation would be opened up if this theory should meet with favor.

In closing, it seems only fair to call attention to one more fact: The main part of the foregoing examples has been directed to the study of moving loads and reversal of loads. The exceptions to, and the limitations of, the theory of limit design have been emphasized to an extent that might well create a false perspective. Suppose a rivet connection, designed according to conventional rules, were subjected to reversal of capacity loads. Unquestionably, the connection would fail after a limited number of such full reversals. The point is that, although reversal of loads and stresses occurs, it seldom occurs for capacity loads. So seldom does it occur that the rules of procedure (that is, the application of the simpler rules of the theory of limit design) are either not affected by it, or affected very little.

Suppose a transmission line were to be covered with a heavy coating of sleet and subjected to a gale from the southwest, transverse to the direction of the line. Suppose, then, if supposition can be so fantastic, that the following year the same sleet condition occurred and the gale blew from the northeast. This is where the suppositions begin to appear absurd. Extreme over-load conditions may occur a few times during the life of the structure. That they occur with the same intensity, the same direction and complete reversal of sense, is against all probability. Even so, according to the theory of limit design they could so occur a few times without disastrous results.

It would seem that the structural engineer has more or less consciously designed in accordance with the principles of the theory of limit design, while paying "lip service" to the theory of elasticity. Is it not appropriate to take stock and develop the theory which most closely fits the facts and appears to have the largest range of application where redundant structures are concerned?

DISCUSSION

John H. Meursinge,[15] Assoc. M. Am. Soc. C. E. (by letter).—Roughly, this paper can be divided into three parts: (1) A criticism of the structural engineers' conventional design methods; (2) a treatise on the theory of limit design, with examples; and (3) a review of the applications of the theory, with references to the proper authorities. All three parts will be discussed in the order mentioned.

(*1*).—In the light of present-day conditions, the harsh criticism of the structural engineers' "love" for stress analyses seems unwarranted because, since the discoveries of Galilei, "all" professions of the civilized world have adopted a number of more or less mathematical rules by means of which the object of their observation is tested. The structural engineer is no exception. Physicians satisfy their urge for numerical terminology by reading thermometers and blood pressure apparatus, and by counting heart beats and white and red blood corpuscles; and economists measure the economic health of the nation by the analysis of the balance sheet. Civilized Man has forgotten entirely that all other living creatures on earth live, multiply, do their engineering work, and die, without worrying about numbers. Their entire existence is based on the application of the laws of equilibrium, efficiency, and usefulness. Nevertheless, the status of their health, economics, and the strength of their structures (as, for instance, the bees) can be perfectly well expressed in terms other than mathematics. If their health is vigorous they carry capacity loads; if their economic system is functioning properly, each member of their society will receive capacity supplies; and, when their engineering structures are in good working order, they will carry capacity loads.

As soon as Mankind adopts such a system, in which his accomplishments are judged by tangible results, the engineer can begin to ignore mathematics. In the meantime, he had better follow the methods and conventions of the society in which he happens to live. Any other course would impair his usefulness seriously.

(*2*).—In the theory of limit design the investigator takes advantage of the ultimate strength of the full cross-section, even when a structure is subjected to bending stresses. There is no more efficient application of the material; and, as a result, structures are obtained, the strength of which can be expressed in capacity loads—that is, in terms of usefulness. Thus far structural designs have merely satisfied a number of mathematical requirements; hence, the theory advanced in this paper is a step in the right direction. The engineer should keep in mind, however, the fact that Hooke's law and the theory of limit design are both "simplifications of a very intricate reality—nothing more nor less. Both may be compared to cartoons, because they both 'express reality in a very primitive manner.'"[16]

[15] Huntington Park, Calif.

[16] "Ductility as a Base for Design Computations of Steel Bridges and Structures Instead of Proportionality of Stress and Strain," by N. C. Kist, International Congress for Metallic Structures, Liége, Belgium, 1930.

Professor Kist taught the writer how to apply the theory of limit design; and, although the examples in the paper had to be quite elaborate in order to clarify the principles for the benefit of new readers, the application can be simplified in practice for the greater part of the problems which the average designer has to solve. For instance, in Case 1 one needs simply to compute the maximum moment of resistance; then immediately draw the moment diagram of Fig. 4; and, apply the static equilibrium formula:

$$w' \frac{L}{2} \times \frac{L}{4} = 2\,M_1 = 60\,000$$

and solve: $w' = 13\,333$ lb.

For concentrated loads: Draw the moment line for capacity loads shown in Fig. 17. Considering the structure as a simple beam with maximum moments of $2\,M$, and calling the end reactions R_1 and R_2: $R_1 = \frac{2\,M_1'}{a}$; and, $R_2 = \frac{2\,M_1}{c}$. By assuming different values for P_1, one can determine the complementary capacity loads P_2.

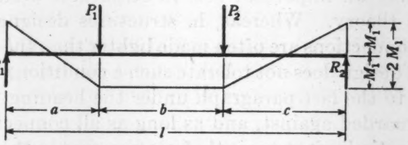

FIG. 17

Professor Van den Broek states that he acquires a factor of safety of 2; but in reality it can be called 3 because Fig. 4 represents a condition in which the cross-section at the middle of the beam still has a triangular stress-distribution diagram. Now, according to the ductility philosophy the beam cannot collapse until two sections have rectangular diagrams; and, as Professor Van den Broek demonstrates in Equation (2), this condition means a 50% increase in strength for rectangular beams.

This simplification of Case 1 is also helpful in solving Case 4, the continuous beams shown in Figs. 9 and 10. First, find the moment of resistance: $\frac{I}{c} = 30$; $s = 30\,000$; and, $M_1 = 30 \times 30\,000 = 900\,000$ in-lb $= 75\,000$ ft-lb. Draw the moment line of Fig. 9(b). Knowing the location of P_1, the computer finds for the left beam reaction: $\frac{75\,000}{5} = 15\,000$ lb. Taking moments about the center support: $15\,000 \times 10 - P_1 \times 5 = -75\,000$; or, $P_1 = 45\,000$ lb.

At first the application of the theory of limit design seems most simple as applied to structures that have no bending stresses, according to the elastic theory method (as, for instance, the tower in Fig. 15); but, if Professor Van den Broek had demonstrated the new method of detailing gusset plates, he would have revealed another radical departure from conventional methods.

(3).—The author considers that the problem of riveted connections is a poor illustration of the application of the theory of limit design (see "Design of Riveted Connections"). For engineers who have had little experience in modern design methods this section happens to be quite convincing. It reveals, plainly, the important fact that designers have to take advantage of ductility (but have not spoken or written about it) in many details, at the same time ignoring it in the design of the main members.

This same chapter, unfortunately, contains a statement from which the reader may infer that the theory of elasticity does not fail as readily in welded connections as in riveted connections. Professor Van den Broek states:

> "Nevertheless, the theory of elasticity fails as completely in the design of rivet connections as it does in the analysis of many other redundant structures.
>
> "Rivet connections appear to be 'giving ground' to welded joints. It may be hoped that they soon will disappear entirely."

H. M. Priest, M. Am. Soc. C. E., has presented[17] stress curves for both riveted and welded connections. In the specimens tested the ends of both connections were over-stressed, and the welded connection would not have held better than the riveted connection except for the ductility of the material.

Connections play an important rôle in structures designed in accordance with the author's theory. Whereas, in structures designed to conform with Hooke's law, the connections are often made lighter than the connected member, the theory of limit design does not tolerate such a condition. Consequently, the writer would add to the last paragraph under the heading "Practical Application": "* * * are guarded against, and as long as all connections are capable of transferring the elastic-limit stresses that may appear in the heaviest connected member."

What about the future of the theory of limit design? An interesting experience of the writer has a bearing on this question. In 1922, while he was a student at the Technical University of Delft, Netherlands, the writer was admonished by Professor Kist for using the elasticity theory of a continuous beam on three supports in order to determine the size of three rollers beneath a shallow roller bearing. Professor Kist demonstrated that the short distance between the actual bearing and the rollers did not give the bearing force in that type of support an opportunity to spread to the two outside rollers until the compression stresses in the middle roller had reached the elastic limit. In this case the theory of limit design offered a more logical solution.

In 1937, the writer, then in the employ of an oil company, was called upon to design a shallow roller bearing beneath a horizontal pressure tank. Remembering his college days, he began with the theory of limit design; but this computation was rejected by the engineer in charge of the design as being contrary to "standard practice." No other action was to have been expected. Hooke's law has been the conventional standard for 250 yr; the new theory is a radical departure from that method. Neither has the new philosophy either established a convenient inter-relationship with modern designers' general process of thinking. Furthermore, the structural engineer's brains resemble a carbureter. After it has been set for a certain mixture of assumptions, it is difficult to adjust it to a new recipe, even if the latter may prove to be more economical.

---

[17] "The Practical Design of Welded Steel Structures," by H. M. Priest, *The Welding Journal*, August, 1933, Fig. 8, p. 9.

Hence the writer has concluded that the theory of limit design will become accepted only gradually. Its extensive application will be postponed until the civilized world has learned that the health and happiness of mankind, as well as the strength of structures, can be expressed in terms of usefulness instead of in mathematical symbols.

I. K. Silverman,[18] Assoc. M. Am. Soc. C. E. (by letter).—The simplest structural form is a straight bar loaded axially. An example is the standard test piece used in determining such quantities as proportional limit, yield point, and ultimate stress. Numerical values of these quantities, obtained from tests on this type of structure, are the bases upon which the proportions of structural members, however they may occur, are estimated.

The proportional limit is defined as that stress at which stress and deformation are no longer connected linearly. The yield point has been defined as that stress at which there is a marked extension with very little increase in load. Sometimes this value is defined as the stress at which a certain permanent strain is obtained. The ultimate stress is determined by dividing the maximum loading recorded in a test by the cross-sectional area of the test piece.

When inserted in codes, these values (which, fundamentally, hold only for the simple case of an axially loaded bar) control the design of as simple a structure as a bar in tension or the relatively complex structure exemplified by a single-span beam.

Assume that instead of the standard test piece a single-span beam of given material, under a given type of loading, is taken as a standard. Then it is possible, in the light of the foregoing definitions, to obtain definite quantities corresponding to proportional limit, yield point, and ultimate strength. It will be found that these values are influenced slightly by the type of loading initially chosen (uniform or distributed) but are greatly influenced by the form of cross-section.[19] E. Mirabelli,[20] M. Am. Soc. C. E., has shown analytically, and has supported his results by citation of tests, that the factor of safety of a beam, based on its own yield point, may be as much as four, compared to a factor of safety of two, based upon the yield point of a simple tensile-stress test.

Although it seems impracticable to test every type of structure to obtain its proportional limit, yield point, etc., this point of view should lead to a new philosophy of design, as the author states.

The results of various tests on standard tensile specimens have led to far-reaching results in mechanical, structural design. It is well known that if a mild steel is loaded in tension above its yield point, unloaded, and then subsequently reloaded, a raising of the yield point is obtained. Along with this raising of the yield point in tension, there is a subsequent lowering of the yield point in compression. This result is known as the Bauschinger effect. In explaining these results, H. Hencky,[21] strangely enough, called upon the phenomena which the author has described. Mr. Hencky's analogy consisted of a three-membered symmetrical truss (Fig. 18(a)), statically indeterminate in the first degree. While the load is $O \leqq P \leqq 2\,s_1A$ (s_1 is the yield point stress in simple tension) an elastic state of stress exists. The load-deformation curve is Line *DF* (Fig. 18(b)). At the load $P = 2\,s_1A$ the vertical bar *DC* (Fig. 18 (a)) becomes plastic and, assuming that the material has a marked yield point, this vertical bar will not increase in stress as the load is increased to, say, $3\,s_1A$. The rate of deflection will be greater, as shown by the slope of *F F′* (Fig. 18(b)). If the structure is unloaded, a permanent deformation corresponding to *D D′* will occur, with residual stresses of tension in Bars *A D*, *B D* and compression in Bar *D C* (see Fig. 18 (a)). If the load is reversed the yield point will be reached at a lower load as shown by *F′F″* because of the

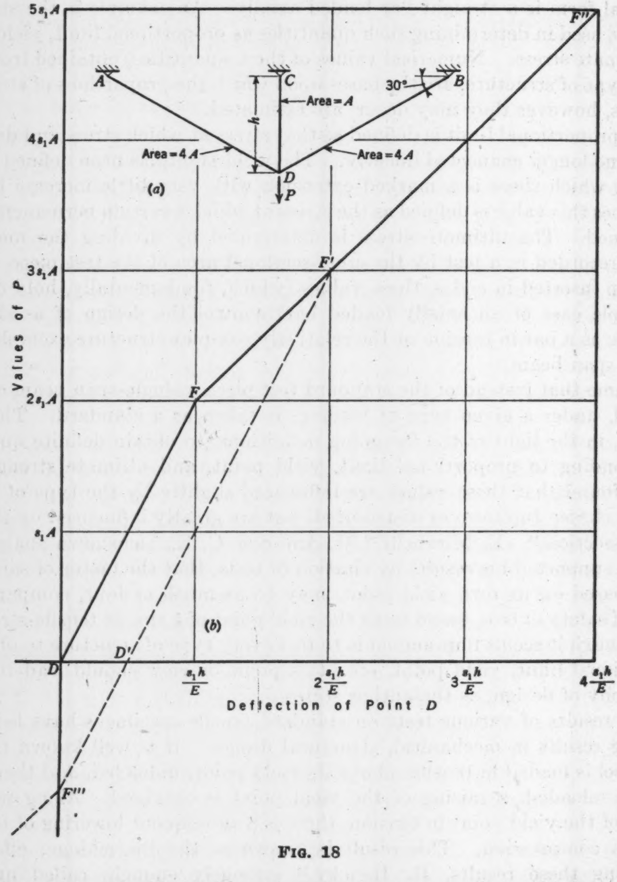

FIG. 18

residual compressive stress in Member $D\,C$. However, if the structure is reloaded in the same direction as the original force, the load will increase along $D'F'$ linearly and will follow along $F'F''$ until all the bars have reached the yield stress s_1. This occurs at a value of the load $P = 5\,s_1A$. Beyond this load, deflections outside the range of magnitude of elastic deformations are to be expected. From the point of view of the theory of elasticity the load capacity of the structure would be taken as $2\,s_1A$. Using the plastic properties of the material the load capacity could be taken as $5\,s_1A$.

The properties given by the simple tensile test, and which have their counterpart in the behavior of the simple structure in Fig. 18(a), have been used advantageously by mechanical engineers. Advantage has been taken of the yielding property of the material and its consequent higher yield point in the design of chains; the favorable residual stresses resulting from permanent deformation have been used in the design of rotors;[22] over-strain of metals has created residual stresses that are favorable during the firing of guns. It is to be noted that in all these cases the direction of the loads is fixed so that the question of reversal does not enter.

The preoccupation of engineers with the concept of stress, as the author states, can be traced to the definition of "factor of safety" as given in textbooks on strength of materials. There, the "factor of safety" is defined as the ratio of ultimate strength to working stress. The idea of stress is intimately connected with this definition. A "factor of safety" based on the ratio of yield stress to working stress is connected with the definition of yield stress which is itself defined in terms of deformation.

The author is to be commended for bringing this subject to the attention of the profession and for his success in clarifying many of the salient points.

EDWARD GODFREY,[23] M. AM. SOC. C. E. (by letter).—The subject of this excellent paper is one that has been neglected or ignored to a large degree by writers on the theory of elastic members. Much has been written on the behavior of materials that are perfectly elastic under the action of stresses, but as there are scarcely any materials that approach this quality there is a hiatus between the theory and the actual fact as represented by the materials under stress. A perfectly elastic material, of which glass is the best example, would be exceedingly dangerous, in many situations, as a structural material.

Professor Van den Broek has cited some cases where the hiatus referred to is most conspicuous. Riveted joints, for example, furnish an example in which the assumption of perfect elasticity would develop, theoretically, a case of certain failure; but failures in riveted joints, where proper rules of design are followed, are totally unknown, and the rules of design virtually ignore perfect elasticity. It is only because structural materials are ductile as well as elastic that they adjust themselves to conditions, and riveted joints designed accordingly, and according to good rules, are safe.

Hencky, *Zeitschrift für angewandte Mathematik und Mechanik*, 1924, p. 331; also "Stress Distribution in Rotating Disks of Ductile Material After the Yield Point Has Been Reached," by A. Nádai and L. H. Donnell, *Transactions*, A. S. M. E., Vol. 51, 1929, APM-51-16, p. 173.

[23] Structural Engr., Pittsburgh, Pa.

The paper also refers to bends in parts that are under high stress, bends that are made on steel when it is cold and that stress the steel beyond the elastic limit. When the bend is not reversed, the steel is safe for unit stresses that would be considered proper in steel that is absolutely straight.

The entire fabric of the theory of secondary stresses, the "Theory of Limit" or, more properly, the "Limit of Theory," falls and fails when it is applied to such cases as stresses due to deflection of rigid structures, stresses due to rotation of members on pins, caused by deflection of a truss, and some other cases.

One of the safest structures in existence is the Firth of Forth tubular bridge, in Scotland, although computed secondary stresses, based on the elastic theory, would show disastrously high unit stresses.

BASIL SOUROCHNIKOFF,[24] ESQ. (by letter).—In the theory of limit design Professor Van den Broek assumes that immediately after a material has reached the elastic yield point, a perfect ductile flow occurs; that is, the material suffers considerable additional deformation, the stresses remaining constant. The stress-strain diagram is composed of two straight lines: Line *A B* corresponds to the elastic phase; and, Line *B C*, parallel to the strain, corresponds to the ductile phase (see Fig. 2). This hypothesis is very interesting. The actual material will probably follow a curve between Line *B C* and the extension of Line *A B* so that the designer can obtain a quite clear insight into the behavior of the structure. Line *B C* is probably limited by some Point *C* where actual rupture occurs after the material has undergone a certain ductile deformation.

The following analysis of a built-in beam, similar to the one analyzed in Case 1 by the writer, will serve to demonstrate the limitations of application of the theory. Suppose a straight beam *A B* of Span *L*, connected at Ends *A* and *B* into rigid supports, and carrying two symmetrical concentrated loads *P* at Points *C* and *D* at distances *a* from the ends *A* and *B* respectively. In this type of loading the moment curve is composed of straight lines, and therefore the algebraic calculations are quite simple.

Increase the loads *P* until the elastic yield point is reached at the supports. The bending moments at the supports (M_0) is then expressed by Equation (1) if s = the yield stress, I = moment of inertia, and c = the distance of the extreme fiber from the neutral axis. The moment at the center is less than M_0. If the loads *P* are further increased, the moment at the center increases. One must assume that the moments at supports also increase somewhat, and that the ductile phase is extended over lengths *A E* and $B F = l$ at each end of the beam. Otherwise, a finite angular deformation would have to occur in an infinitely small length of the beam, which is improbable (see text preceding Equation (2)).

The loads *P* are now increased until the moment in the central part almost reaches the value M_0 as defined herein. The moments at the supports are then κM_0, κ being a coefficient greater than unity. The lengths at each end of the beam where ductile flow occurs, can be calculated easily by noting that the moment diagram is a straight line, and that at Ends E and F of the lengths l the moment is M_0; thus:

---

[24] Structural Engr., St. Paul, Minn.

$$\overline{A\,E} = \overline{B\,F} = l = a\,\frac{\kappa - 1}{\kappa + 1} \dots\dots\dots\dots\dots\dots (6)$$

In the region $E\,F$ the material is completely in an elastic state and it is easy to find the slope α of the deformed axis of the beam with the horizontal at Points E and F; thus:

$$\alpha = \frac{M_0}{E\,I}\left(\frac{L}{2} - a\right) = \frac{s}{E}\,\frac{b}{c} \dots\dots\dots\dots\dots\dots (7)$$

in which $b = \frac{L}{2} - a$. The change of slope in each of the lengths l must be arithmetically equal to α as the beam is built into rigid supports. The average change of slope, per unit length, in the region where ductile flow occurs is, therefore,

$$\frac{\alpha}{l} = \frac{s}{E}\,\frac{b}{c\,a}\,\frac{\kappa + 1}{\kappa - 1} \dots\dots\dots\dots\dots\dots (8)$$

At the points when the unit change of slope is the greatest its value α_M is obviously greater than the average, so that $\alpha_M > \frac{s}{E}\,\frac{b}{c\,a}\,\frac{\kappa + 1}{\kappa - 1}$. Assuming that κ is greater than one, the minimum value of α_M is obtained by selecting the greatest possible value of κ. For a rolled beam, 12 in. by 12 in. by 65 lb, the greatest possible value of κ is 1.0662 (see last line of Case 1) and therefore the smallest value of $\frac{\kappa + 1}{\kappa - 1}$ is about 30. Consequently, $\alpha_M > 30\,\frac{s}{E}\,\frac{b}{c\,a}$. Now, independently of the system of loading, the unit change of slope at any point cannot be greater than a certain value α_x, which is dependent on the properties of the material and of the cross-section. The length of an extreme compressed fiber, originally equal to one, cannot be reduced to less than zero. The length of the extreme tension fiber, originally equal to one, cannot be stretched beyond a certain value u before a break occurs. Therefore, $\alpha_x < \frac{u}{2\,c}$. If, therefore, there is a ductile flow, but no actual break of fibers occurs in any place, one must have: $\alpha_M < \alpha_x$; therefore, $30\,\frac{s}{E}\,\frac{b}{c\,a} < \frac{u}{2\,c}$; and, $\frac{u\,E}{s} > 60\,\frac{b}{a}$.

Symbols u, E and s depend on the properties of the material only; b, a, c on the dimension of the beam and the positions of loads only. For a given material the value of $\frac{u\,E}{s}$ is given, and it seems, therefore, that (theoretically at least) one can determine a certain position of the loads for which, as the load is increased, a break at the supports will occur before the yield point is reached at the middle.

Reference to questions of this type was probably made when the author stated that he intentionally omitted studies of certain secondary considerations, thus diverting attention from the essential arguments (see text preceding Equation (2)).

Of course, if a few extreme fibers are broken at the supports, it does not mean that the entire beam will collapse; but permanent cracks will be formed and may be easily aggravated by frost, etc. The resistance to shear may also be impaired.

E. Mirabelli,[25] M. Am. Soc. C. E. (by letter).—As applied to flexural members, the author's theory of limit design appears to provide an ample degree of safety. The theory is based on the conservative assumption that the yield point in bending is reached when the outer fibers begin to yield. Actually, beam deflection does not increase rapidly with a small increment of load until there is a considerable excess in the loading beyond that which causes yielding in the outer fibers. The load-deflection curve for a simple beam continues as a straight line (or very nearly a straight line) within the order of magnitude of elastic deflections during the period of time that the plastically stressed region in the beam extends from the outer fibers toward the neutral axis. Eventually, a loading is reached at which the beam deflection increases rapidly. The amount of this loading depends on the shape and proportions of the beam. These facts have been demonstrated mathematically elsewhere.[26] For these reasons the actual amount of the margin of safety exceeds the assumed amount and the theory of limit design seems justifiable when applied to beams.

However, the new theory does not seem to be so easily acceptable when applied to frames which involve direct stress. In connection with indeterminate trusses, the theory is that any over-stressed member of the frame will continue to carry its share of the load at a constant capacity, while the member is being distorted until the capacity load is fully applied to the frame. A tension member may act in such a manner, but it is doubtful that a compression member is capable of carrying a constant amount of load after the yield point of the material is reached. An over-stressed compression member is likely to have a total resistance less than its capacity at the yield point (if it does not buckle and fail completely). This means that the other members of the frame must carry more than their design load. A reduction in the margin of safety is involved thereby.

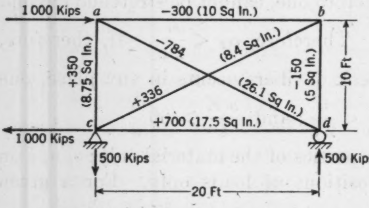

FIG. 19.—STRESSES BY LIMIT DESIGN THEORY OR BY ELASTIC THEORY

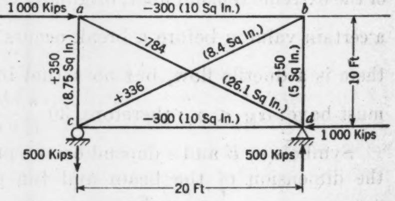

FIG. 20.—STRESSES BY LIMIT DESIGN

---

[25] Associate Prof. of Civ. Eng., Mass. Inst. Tech., Cambridge, Mass.

[26] "Structural Application of Steel and Light-Weight Alloys: A Symposium," *Transactions*, Am. Soc. C. E., Vol. 102 (1937), pp. 1397–1403.

In the type of indeterminate truss shown in Fig. 19 any stress may be assigned to any member (such as − 300 kips to Member *a b*) and the stresses in the remaining members may be determined by application of the static conditions of equilibrium at successive joints. This is essentially the procedure of the theory of limit design. If, now, the required cross-section areas are determined from these stresses and the truss is analyzed by an elastic theory, it is found that the bar stresses are the same as those determined by application of the limit design theory. For such a case the two theories lead to the same design. The only difference is that the use of the new theory involves some saving in the time required for making the analysis.

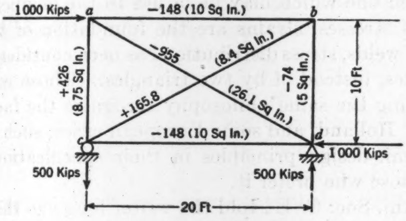

FIG. 21.—STRESSES BY ELASTIC THEORY

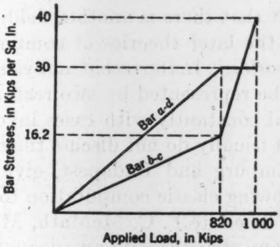

FIG. 22

Now, if the type of structure is changed by interchanging the hinged and roller supports, the elastic analysis and limit design analysis will not result in the same bar stresses. The stresses obtained by the limit-design method are shown in Fig. 20 and those found by the elastic method are shown in Fig. 21. The cross-section areas of members are assumed the same for the two cases. Diagonal *a d* will attain its capacity of − 784 kips when the applied load is $1\,000 \times \frac{784}{955} = 820$ kips. Until this loading the stresses are within the elastic range throughout the frame, and at this loading the stress in Diagonal *b c* is $165.8 \times \frac{820}{1\,000} = +\,136.0$ kips. According to the new theory, Member *a d* will continue to offer its capacity resistance of − 784 kips while the applied load is increased from 820 kips to 1 000 kips; and, the stress in Diagonal *b c* is increased from + 136.0 kips to + 336.0 kips. This theoretical action is shown graphically in Fig. 22, in which stress intensities are used instead of total stresses.

The writer feels that there is no justification for assuming that the *a d*-line (Fig. 22) will continue horizontally at the level of 30 000 lb per sq in. Probably, there is more reason to believe that at the applied load of 820 kips the *a d*-line will reverse its direction and dip, or that Member *a d* will be completely destroyed by buckling. As a consequence, the assumed margin of safety will be reduced, although it is true that in the majority of cases it is not likely that failure will occur at the working loads.

Possibly such objections could be overcome by use of a larger factor of safety for compression members than for tension members. However, if this were done, the economy in material effected by the application of the limit design method would be neutralized to some extent. The principal virtue of the new method, when applied to trusses, would then be in the simplification of stress analysis.

C. M. GOODRICH,[27] M. AM. SOC. C. E. (by letter).—Clearly and cogently, Professor Van den Broek has directed attention to the unfortunate change that the teachers, and the present generation in general, have made in Hooke's law, from *ut tensio sic vis* (as strain, so stress), to *ut vis sic tensio*. It is equally clear from his paper that no fault is found with any elastic theory in its proper field—namely, within elastic limits. He directs attention merely to the undoubted fact that there is another field, and one which may be of use to the engineer. In the later theories of combined stresses, strains are the foundation of the theories. In the recent analysis of welds, stress distribution has been considered to be represented by two rectangles, instead of by two triangles. Those who deal constantly with cases involving the same philosophy recognize the facts but usually do not discuss them. Holland, and some European cities, such as Hamburg and Budapest, give limit-design principles in their specifications, allowing elastic computation to those who prefer it.

The late F. C. McMath, M. Am. Soc. C. E., told the writer long ago that, in any structure, if any adequate path is provided to enable forces to reach the ground, any other path or paths taken will lessen work required of the structure as a whole. In one standard reference book[28] appears the statement, "These proximate solutions are offered as illustrative of simple approximate methods which may often be applied to very complicated problems of this class." In other words, this author recognizes the principles of what Professor Van den Broek has aptly called "limit design."

In a German work,[29] Föppl describes the treatment of structures over a street to protect traffic from falling objects, including this comment: "Accordingly, it is sufficient to equate the energy of the falling mass (after deduction of the impact-loss), with the form-changing work that must be expended in bending the beam severely, and it is sufficient to require that the impact loss does not exceed a reasonable fraction of the work expended." In addition, Föppl refers to A. Senft,[30] who apparently treats the subject more fully. He then cites the further case of bomb shelters, where also, clearly enough, limit-design principles were used. It is unfortunate that the logic of the case was not developed to show its many possibilities.

In 1910 designs for transmission towers were prepared by the writer's Company, using limit-design ideas freely. These designs, doubtless because of their unconventionality, were condemned by a succession of five different eminent authorities as inadequate to sustain the required load. Two sample structures, built to these designs and tested at the expense of the company, showed a load capacity about 50% in excess of that required as a minimum.

Structures containing more than 7 000 tons, built under one contract to these and to similar designs and employing such methods as are advocated by Professor Van den Broek, are in service to-day. Even yet such steel is often sold under a guarantee that the structures will carry the required loads under test, usually plus some fixed percentage. This guarantee obviates a not improbable condemnation should the designs themselves be submitted for approval.

The logic of limit design is inescapable; its application is simple; and it promotes economy. In such a field as that of rivet groups under alternating stresses it exposes a danger not discussed in current textbooks, and not at all adequately explored in testing laboratories. These principles are under a kind of tabu, apparently, although they are familiar enough in some of their practical expressions. To determine their field of usefulness makes it necessary to open the windows of the mind, and to encourage a frank discussion of "whens" and "whys."

George Winter,[31] Esq. (by letter).—The writer has known the "theory of limit design" ever since Bleich[32] in 1932 developed a method similar to that proposed by the author. The fundamental principles underlying both of these methods are indeed extremely appealing to engineering common sense. Professor Van den Broek is to be commended for introducing this topic for discussion and thus opening new prospects for a more exact theory of design based on the criterion of permissible deformation.

However, in the author's treatment (as well as in Bleich's) it is precisely the question of deformation which, in the last analysis, remains unsolved. Any design theory that does not provide the means of determining the deformations corresponding to any given load up to the ultimate one is incomplete and questionable. It is the indisputable strength of the theory of elasticity that it provides these means with a high degree of accuracy. Any design theory extending beyond the elastic range should attempt, at least, to satisfy this same condition, and even more so a theory which consciously assumes as its base the criterion of permissible deformation. This is not the case either in the author's theory or in Bleich's (the only one which formerly was known to the writer).

Realizing this deficiency the writer, in November, 1938, undertook to investigate the bending of steel beams beyond the elastic limit with the main purpose of its application to what the author, very exactly, calls "limit design." The writer intends to discuss herein only those aspects which bear a direct relation to the theory advanced for discussion by Professor Van den Broek. The most important question to be solved seems to be that of determining the deflection of beams, thus "over-stressed," in a manner similar to the determination of purely elastic deflections.

For his investigation the writer has used the same type of idealized stress-strain diagram Fig. 23(a) that underlies the author's and Bleich's theories as well as other treatments of plastic bending.[33] Fig. 24(b) represents the stress distribution over a cross-section after the elastic limit has been exceeded. At a distance 0.5 q above and below the neutral axis the magnitude of the unit fiber strain is ϵ_e. Hence the differential equation of the bent axis of such a beam is

$$\frac{d^2y}{dx^2} = -\frac{2\,\epsilon_e}{q} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

in which $\frac{d^2y}{dx^2}$ is the curvature of the axis, ϵ_e the elastic limit strain (see Fig. 23(a)) and q the depth of the part of the cross-section within which the stresses are less than the yield point s_y—and, hence, where they obey the straight-line law (see Fig. 24(b)). As usual it is assumed that plane cross-sections remain plane if subject to this stress distribution, a fact which has been well confirmed experimentally in the plastic, as well as the elastic, range.[33] Since the moment of the external forces must be balanced by that produced by the stress distribution shown in Fig. 24(b), a simple equation of equilibrium determines q for any given moment. In this manner the writer has found for rectangular cross-sections

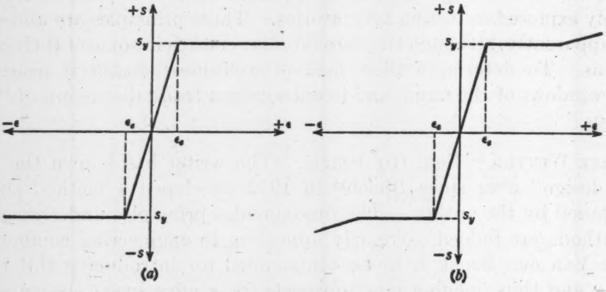

FIG. 23.—IDEALIZED STRESS-STRAIN CURVES

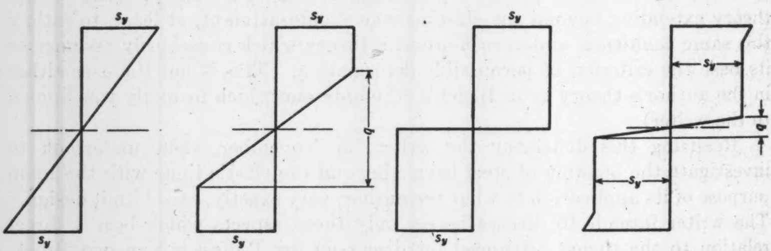

FIG. 24.—CONSECUTIVE STRESS DISTRIBUTIONS IN BENDING BEYOND THE YIELD POINT

$$M = \frac{s_y}{4}\,b\left(h^2 - \frac{q^2}{3}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

and for I-beams (see Fig. 25):

If $q \leqq h_1$,

$$M = s_y\left[b\,d_1h_2 + \frac{d_2}{4}(h_1^2 - q^2) + \frac{d_2q^2}{6}\right]\dots\dots\dots\dots(11a)$$

and, if $q \geqq h_1$,

$$M = s_y\left[b\,\frac{h^2 - q^2}{4} + \frac{b\,q^3 - (b - d_2)\,h_1^3}{6\,q}\right]\dots\dots\dots\dots(11b)$$

Obviously Equations (10) and (11) hold as long as the stress distribution of Fig. 24(b) holds and hence can be evaluated as long as $q \neq 0$. On the basis of the stress-strain curve of Fig. 23(a) q becomes zero when the moment of the external forces becomes equal to the internal moment corresponding to the stress distribution of Fig. 24(c). It is obvious that in this case

$$M = s_y\,S_p\dots\dots\dots\dots\dots\dots\dots\dots(12)$$

in which the section modulus S_p is twice the moment of the area of the upper or lower half of the cross-section about the neutral axis; S_p will be called the plastic section modulus as compared with the usual elastic section modulus S_e. The ratio $S_p : S_e$ depends largely upon the shape of the cross-section; it is 1.5 for rectangular beams, 1.136 to 1.195 for standard I-beams and 1.07 to 1.175 for wide flange sections. If the moment of the external forces at any section reaches the value given by Equation (12), this section has reached its ultimate bearing capacity. It is transformed into a "plastic hinge"; that is, the two parts of the beam at both sides of this cross-section can be rotated with respect to each other through a considerable angle without increasing the load, the internal moment remaining unchanged during this rotation.

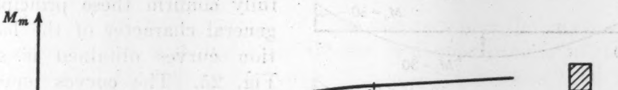

FIG. 25.—LOAD DEFLECTION CURVES OF A RECTANGULAR BEAM AND AN I-BEAM HAVING THE SAME SECTION MODULUS, S_e, AND THE SAME YIELD POINT, S_y

It may be noted that, actually, the state of an ideal "plastic hinge" can be approached but can never be reached completely, the reason being that the curve in Fig. 23(a) is idealized and for more accuracy should be replaced by Fig. 23(b) which includes work hardening. Then, instead of the stress distribution in Fig. 24(c), that in Fig. 24(d) will occur, in which q can never be zero, although it becomes very small for ordinary ductile structural steel. However, it may be shown from Equations (9) to (11) (as well as from tests performed by the writer) that the difference between the idealized and the actual state is negligible. In fact the difference between the moment of Distribution 24(c) and the actual moment at which Distribution 24(b) changes to Distribution 24(d) does not exceed a fraction of 1% and, from this load on the section, may be regarded as a "plastic hinge" with about the same degree of accuracy.

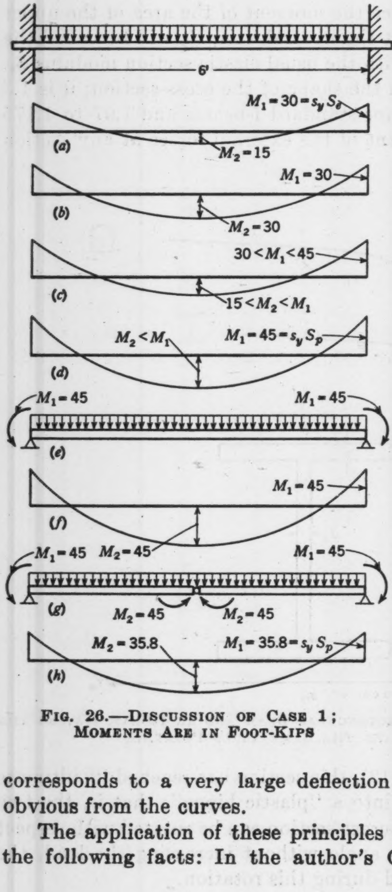

FIG. 26.—DISCUSSION OF CASE 1; MOMENTS ARE IN FOOT-KIPS

The writer has tested the foregoing ideas experimentally by means of bending tests performed on I-beams as well as rectangular beams. Although this investigation is not yet finished (1939), the results hitherto obtained fully confirm these principles. The general character of the load-deflection curves obtained is shown in Fig. 25. The curves represent the mid-span deflection of an I-beam and a rectangular beam both having the same section modulus S_e. Point a, Fig. 25, corresponds to the maximum moment $M_m = s_y S_e$—that is, to the ultimate elastic load, or moment, at which the transition from Stress Distribution 24(a) to Distribution 24(b) occurs; Points b correspond to $M_m = s_y S_p$—that is, to the transition from Distribution 24(b) to Distribution 24(d), or to the moment at which a "plastic hinge" is formed. The experimental curves between Points a and b show good coincidence with the ones computed from Equations (9) to (11). The parts of the curves above Point b, Fig. 25, show that the idea of a plastic hinge is justified because from that point a very small load increment corresponds to a very large deflection increment. The importance of S_p is obvious from the curves.

The application of these principles to the "theory of limit design" reveals the following facts: In the author's Case 1 (on which the other cases are based so far as bending is concerned), the moment distribution of Fig. 26(a) is the ultimate one which is governed by the usual principles of the theory of elasticity and ordinarily is regarded as the limit so far as bearing capacity is concerned. Professor Van den Broek proposes to take the moment distribution of Fig. 26(b) as the ultimate, and to base the safety factor on this distribution. However, Distribution 26(a) is defined exactly; it actually occurs whereas it is easy to show that Distribution 26(b) never can occur. If, after having reached Distribution 26(a), the load increases further, the end moments increase as well as the mid-span moments. Whereas the latter still remain in the elastic range, however, the end moments exceed $M = s_y S_e = 30\,000 \times \frac{12}{12} = 30\,000$ lb-ft—in other words, Distribution 24(b) takes place. Regarding Fig. 25 as the curve of relative rotation of two consecutive cross-sections as plotted against *M*, the parts of the beam near the ends are in the section *a-b* of the curve, whereas the mid-span part is still in section *o-a*. Hence the deformations of the former are governed by Equation (9), and those of the latter by the usual relation

$$\frac{d^2y}{dx^2} = -\frac{M}{EI} \qquad \text{(13)}$$

The essential point is that by means of these two relations the entire state of deformation as well as of moment distribution is defined exactly in the same manner as it is defined in the elastic range by Equation (13) alone. On further increasing the load, Moment M_1 finally reaches its ultimate value, $M = s_y S_p = 30\,000 \times \frac{18}{12} = 45\,000$ lb-ft (corresponding to Fig. 24(c) and Equation (12) and the end sections become transformed into "plastic hinges" (see Fig. 26(d)). The beam from now on acts as if it were freely hinged, with constant restraining moments at the supports (see Fig. 26(e)). In this state the moment distribution is determined by simple equilibrium relations and the deflections are still determinable by Equations (9) and (13). After a further increase of the load the mid-span section finally reaches its ultimate moment also, another plastic hinge forms at this point (see Figs. 26(f) and 26(g)) and, any slight further increase of the load results in excessive and uncontrollable deformation. In this entire process the deformations remain in the order of elastic deformations until shortly before the load corresponding to Fig. 26(f) is reached. (The foregoing idea is the one underlying Bleich's theory. The difference between his treatment and the one presented herein is that Bleich did not take into consideration the foregoing developed laws governing the deformations and moment distributions during the entire process. The method of integrating simultaneously the differential Equations (9) and (13) over the entire span is essentially the same as that used in the ordinary theory of elasticity for the integration of Equation (13) only. Moreover, the equations developed herein are still, fundamentally, elastic equations since the deformation is governed by the central part of the cross-section within *q* [see Fig. 24(b)] which remains elastic until the ultimate load is reached. However, the actual computation is somewhat cumbersome and exceeds the scope of this paper.)
